FOREWORD

Grains are the staff of life. Mindful of this, it is impossible to contemplate a world devoid of grain. The efficient production and processing of grain are critical activities that are sustained by science. Indeed, it has been said that efficient technology is essentially the science that works.

Grain science is the driving force behind the efficient use of grain. The beginnings of grain science are lost in antiquity. However, the research literature and the practices used for processing all the grains of the world are wide-ranging, disparate, and complex. The transfer of scientific knowledge that relates to food raw materials is essential and important for the improvement of world health. In order to collate and present current knowledge and the future potential of grain science to the world, a group of distinguished experts were assembled to produce this *Encyclopedia of Grain Science*.

This remarkable and unique work of science and scholarship comes in three volumes and covers all aspects of grain science. It is always important that scientific information is presented in a logical and reader-friendly manner. The *Encyclopedia of Grain Science* is beautifully produced and easy to read. Related chapters are cross-referenced and the authors have presented the science and associated technology of their chapters in a manner that is accurate, informative, and clear.

It is difficult to predict how often this encyclopedia will be consulted for ideas, information, and clarification of any aspect of the production, processing, and use of grains worldwide. However, with regard to a complex and wide-ranging subject such as grain science, a readily available single source of information is an essential requirement for all those who produce and process grains in industries such as food-making, farming, animal-feeding, grain-breeding, baking, brewing, distilling, and marketing. This book is a uniquely important source of reference for teachers and academics involved in teaching, and research and development of grain science and technology. Students, consultants, politicians, historians, and the general public will find this publication useful as regards the accessing of information on grain that would require an extensive search of literature that is not readily available. Those involved in related sciences and industries should regard this book as a valuable source of comparative information on biotechnology and processing, especially as regards foods, drinks, and beverages. The reference section of each chapter is designed to direct users to important articles that will elaborate further on the science, technology, and methodology of summarized information.

Having had the privilege to be involved in grain science and technology for a long time, I have been associated with many books that deal with grain science. The *Encyclopedia of Grain Science*, without doubt, will take its place as one of the great books of the world of grain science. It is written by experts dedicated to the important aim of improving grain quality and availability in a world that regards grains as its primary food source.

PREFACE

Grains have always been critical to mankind's existence. The word "bread," the most obvious product of grains, has become synonymous with food, as indicated by the motto of the United Nation's Food and Agriculture Organization: "Fiat panis," meaning "Let there be bread." Primitive humans relied on grain found wherever it grew until the dramatic discovery that some of this grain, if planted and nurtured, would produce a crop that could be harvested and stored to sustain the family from one harvest to the next. The cultivation of grains was thus the critical development that changed human from the hunter–gatherer nomad into the settled agriculturalist, leading in turn to opportunities for cultural activities. The accompanying breakthroughs were the discoveries of tools and processes to make the harvested grains more tasty and nutritious, namely, the processes of crushing and sieving, and of mixing the resulting flour with water and baking the dough to make primitive forms of bread or porridge.

Since those early days, there have been great improvements in all aspects of grain science and technology. Today, a wide range of grain species is exploited in all countries of the world. These include the cereal grains, the legumes, and the oilseeds. Their breeding, production, transport, and processing are very big business worldwide, irrespective of whether the country is a net importer or exporter. Although much of world grain production is consumed close to the site of production, large excesses of production over consumption in several regions mean that world trade in grains is also very big business. Methods of processing in today's world cover the full range from traditional methods, handed down through many generations, to very sophisticated large-scale factories. Throughout this diversity of approaches to grain utilization, grains supply a great proportion of the world's food – both as energy and protein sources. Grains also make a major contribution to our diet via grain-based feedstuffs for animals. A significant proportion of grain production goes for industrial uses, thereby contributing to the wider range of our foods (e.g., margarine, sweeteners in drinks, and protein supplements in meats and in synthetic milk drinks), as well as entering an amazing diversity of non-food applications (e.g., adhesives, plastics and paper products).

Our main aim, in compiling this encyclopedia, was to cover everything in the complex range of topics that a true *Encyclopedia of Grain Science* should offer. This diversity is three dimensional:

1. One axis covers the wide range of grain species, especially those of economic value to mankind and his general environment. These include the cereal grains, the oilseeds, the pulses (grain legumes), the soybean (which is both a pulse and an oilseed), the pseudocereals, as well as amaranth and quinoa.
2. The second dimension covers the sequence of events that is common to all grains, namely, breeding and selection, the production of seed for sowing and the grain for harvest, harvesting, storage, transport and marketing of the grain, and finally processing of the grain to produce food and feed products.
3. A third axis also considered involves the diversity of scientific disciplines used to investigate the questions arising from the study of grains at all stages of their production and utilization.

By the use of a comprehensive review process and the careful selection of authors, every effort has been made by the Editors and the distinguished Editorial Advisory Board to ensure that the *Encyclopedia of Grain Science* covers this wide diversity of topics and is accurate, readable, and up-to-date. The work is also extensively cross-referenced and indexed to ensure that the reader is able to easily locate information as needed.

Readers are invited to enjoy using this encyclopedia. We hope that they be rewarded by the discovery of valuable information, authoritative answers to perplexing questions, and pictures – in words and in actual illustrations – pictures that take the reader to the ends of the Earth, or maybe just down the street.

So, bite into a slice of freshly baked bread, spread with canola margarine or peanut butter, washed down with barley-brewed beer and consider that in this encyclopedia all the known answers are provided to tell the story of how these appetizing foods reach your dinner table.

Introduction

Amaranth is a rediscovered "new" crop. It was an ancient crop that was under cultivation 5000–7000 years ago as a staple food of the ancient Aztecs. Amaranth was long forgotten partially because it was prohibited for food use due to religious reasons after the Spanish conquest of the New World. Nowadays it is still cultivated as a minor crop in Central and South America and some areas of Asia and Africa. Since the late 1970s, it has been consistently observed that amaranth possesses characteristics of fast growth rate, good tolerance to stress (drought, salinity, alkalinity, acidic, or poor soil), and high potential for biomass and grain yield. Amaranth is a pseudocereal crop and produces cereal-like grains that contain high levels of nutritionally favorable protein, unusual quality of starch, and high-quality oil (including squalene). Amaranth grains can be used for foods and its vegetative parts can be used for animal feed (e.g., forage, silage) or green manure. The red-colored vegetative tissue produces high levels of betacyanin pigments that can be used as natural food colorants. Amaranth has been attracting worldwide attention as a high-potential new crop with multiple uses.

Amaranth Production and Development

Although amaranth has long been cultivated as a minor crop in Central and South America and some areas of Asia and Africa, its production has rapidly expanded since the early 1980s, particularly in developing countries. In many countries – especially in Asia and Africa (e.g., China, India, Nepal, Ethiopia, and Kenya) – introduction, cultivation, and development of amaranth have been undertaken. Since 1982, the Chinese Academy of Agricultural Sciences has introduced hundreds of amaranth lines/varieties from the United States and other countries into China. Some selected superior varieties (e.g., R104 and K112) have been successfully grown in over 20 provinces. Amaranth has attained great popularity in China for use in feed and food and for other purposes. Current rapid mass expansion of amaranth is mainly for use as a feed crop for animal production. Amaranth production in China has now reached ~300 000 ha annually, ranking as the top amaranth producer in the world. The amaranth production in Russia is estimated to be more than 100 000 ha, and some significant production in India and Mexico is expected as well. Despite the fact that in China and Russia there is larger-scale cultivation of amaranth mainly for feed use, there is still appreciable commercial cultivation of amaranth for human nutrition in Mexico, South American countries, China, USA, Poland, Austria, etc.

There is considerable variation in amaranth yield per hectare in different countries. In China, depending on environmental conditions and cultivation systems, field production may yield ~2200–5500 kg ha^{-1} of amaranth grain, and ~90 000–180 000 kg ha^{-1} of fresh plants (silage). During cultivation trials, ~3000 kg ha^{-1} is achieved with good agronomic practice and good seed sources, and even a maximum yield of 4000 kg ha^{-1} has been obtained in Montana, USA, and 6000 kg ha^{-1} in Peru. There was an average yield of 2250 kg ha^{-1} in the northwest hills of India and 2000 kg ha^{-1} in Austria.

In the USA, extensive research work on amaranth has been conducted, especially under an amaranth research program at the Rodale Research Center, which started in 1976 and lasted for 14 years. Richest genetic resources of *Amaranthus* from many countries and regions in the world were collected and introduced. Special breeding varieties and different products have been developed, which are sometimes sold in health food shops or supermarkets. Although amaranth cultivation in the USA ranges from the Great Plains to the Rocky Mountains in Colorado, production is very limited, with perhaps only a few hundred

acres planted. Notably, through collaboration of scientists from all over the world, initiated by this center, amaranth development has been stimulated worldwide.

Research and development of grain amaranth in China, amaranth biology, chemistry, and processing, and other technology have been summarized and reviewed. A series of studies on *Amaranthus* have been carried out recently at The University of Hong Kong. These references and researches demonstrate the unusual properties of *Amaranthus* starch, protein, oil, and pigments, and reveal their potential for use as food, being helpful to enhance future development and utilization of amaranth.

Biological and Agronomic Characteristics of Amaranth

Amaranth, a pseudocereal crop, is a dicotyledonous C4 plant belonging to the genus *Amaranthus* (which consists of some 75 species) of the family Amaranthaceae. There are two major types of amaranth: grain amaranth (e.g., *A. cruentus* L., *A. caudatus* L., *A. hybridus* L., and *A. hypochondriacus* L.) and vegetable amaranth (e.g., *A. tricolor* L., *A. dubius* L., and *A. lividus* L.). Grain amaranth is believed to originate from Central and South America, whereas the main vegetable types are believed to originate from Southeast Asia.

Amaranthus plants usually prefer hot, bright sunlight and are distributed from the tropics through the semiarid regions. Cultivated species can grow in the tropics, subtropics, and temperate zones, and grow well even in some cold areas such as Nepal and Chinese Tibet. Amaranth possesses high yield potential and high stress tolerance to drought, salinity, alkalinity, or acidic soil conditions. It typically gives a grain yield of 2250–4500 kg ha^{-1} and a fresh leaf-and-stem weight of 30 000–60 000 kg ha^{-1}.

The amaranth plant varies from branched to unbranched, prostrate to erect, and dwarf to over 4 m in height. The leaves are normally elliptical, with an acute tip and a cuneate base; leaf size varies significantly between and within species. The flowers are indefinite inflorescences. Amaranth seed morphology is unlike common true cereal grains. Seedcoat color ranges among black, brown, yellow, and white. Seed embryo is campylotropous, i.e., circular, with the ends nearly touching and enclosing the perisperm (Figure 1). The seeds are extremely small, with 0.5–1.2 g per 1000 seeds or 850–1700 seeds per gram (30–70 times smaller than a typical wheat grain). A single plant can produce more than 500 g of grains. However, in actual field production, seed yield of amaranth varies greatly (15–50 g per plant), depending on the varieties used and soil fertility conditions.

Composition of Amaranth Grains and Vegetative Tissues

Grains

Amaranth is one of the few multipurpose plants that can supply grains and leafy vegetables of high nutritional quality for use as food and feed. Amaranth grain is characterized by a relatively higher content of protein, higher lipid content, and lower starch content than those of the major cereals. A comparison of the average chemical compositions between amaranth (*A. hypochondriacus*) and main cereals (maize, rice, and wheat) is shown in Table 1. Table 2 shows the proximate chemical compositions of the grains of several *Amaranthus* species, indicating that there is some variation within an overall pattern among and within species.

Total dietary fiber content (soluble and insoluble) in amaranth grains from *A. caudatus*, *A. cruentus*, and *A. hypochondriacus* ranges between 7.1% and 16.4%. The nonstarch polysaccharides make up ~6–7% in the light-colored or dark grains. The content of various mineral elements and vitamins in amaranth grains from major species was analyzed. The levels of P, Ca, K, and Mg are usually higher than those found in common cereal grains. The P/Ca ratio varies from 1.9 to 2.6. It is of nutritional interest to find that amaranth grains contain relatively higher level of iron than that in cereal grains. Amaranth grains are relatively high in tocopherol (546 ppm), riboflavin, etc.

Leaves

Amaranth leaves contain 27.8–48.6% dry matter as crude protein and, on average, have somewhat more protein than spinach, as shown in Table 3. The fat content ranges from 2.9% to 7.1% and contains linoleic acid as the major concentration of unsaturated fatty acid (40–55%) and palmitic acid as saturated fatty acid (18–25%). Amaranth leaves and stems are a very good source of fiber (11.1–22.9%). Minerals – such as P, Fe, Mg, and Ca – also exist in high concentrations, giving a total of 33.1–40.7% of ash content. Vitamins C and A are in concentrations of nutritionally significant levels, averaging 420 and 250 ppm, respectively. Seedlings, leaves, and stems of amaranth extensively save as tasty vegetables and animal feeds in the numerous places of the world, especially in China, India, and Southeast Asia. The protein isolated from leaves of *Amaranthus*

species is rich in lysine (6.2–6.8%), higher than that of alfalfa, cabbage, and maize. It also has relatively good amounts of other amino acids. The edible and nutritional quality of vegetable amaranth is almost equal to spinach.

In addition, recently it has been found that red-colored vegetative tissues (seedlings, leaves, inflorescences, etc.) of *Amaranthus* species contain high level of betalain pigments as natural colorants. There has also been much information on other compounds in amaranth (tannin, phytic acid, oxalate, saponins, nitrates, trypsin inhibitor, etc.) with antiphysiological activity in animal performance. Tannins are of importance from the nutritional point of view, since they may influence protein digestibility and reduce mineral bioavailability. Tannins in different amaranth species range between 0.1% and 0.25% and seem to be low enough not to have nutritional impact. The phytate content (0.34–0.61%) in amaranth is higher than that found in rice (0.1–0.14%), but lower than that detected in maize and wheat.

Amaranth Starch

Starch is the main component of amaranth grain, composing ~48–69% of its total dry weight. Starch generally consists of straight-chain and branched-chain molecules, i.e., amylose and amylopectin.

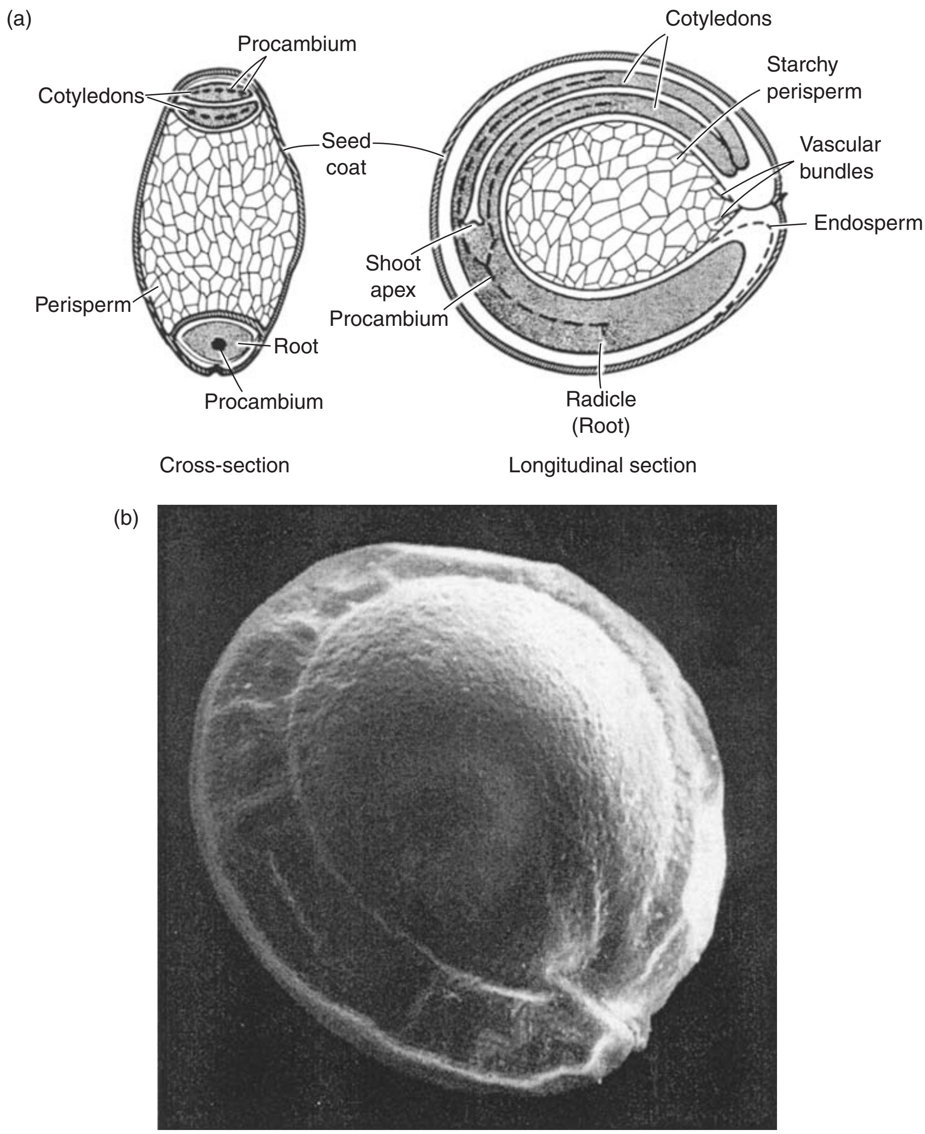

Figure 1 (a) Illustration of *A. cruentus* seed in cross- and longitudinal sections; (b) scanning electron micrograph of *A. cruentus* seed. (Adapted from Irving DW, Betschart AA, and Saunders RM (1981) Morphological studies on *Amaranthus cruentus*. *Journal of Food Science* 46(4): 1170 and Becker R (1994) Amaranth oil: composition, processing, and nutritional qualities. In: Paredes-López O (ed.) *Amaranth: Biology, Chemistry, and Technology*, p. 135.)

Table 1 Comparison of proximate composition between amaranth grains and some cereals[a]

Composition	*Amaranth*[b]	*Wheat*	*Corn*	*Rice*
Carbohydrate	59.2	66.9	67.7	75.4
Crude protein	16.6[c]	14.0[d]	10.3[e]	8.5[e]
Fat	7.2	2.1	4.5	2.1
Crude fiber	4.1	2.6	2.3	0.9
Ash	3.3	1.9	1.4	1.4
Moisture	9.6	12.5	13.8	11.7

[a] Percentage on dry weight basis; data from Saunders RM and Becker R (1984) *Amaranthus*: a potential food and feed resource. In: Pomeranz Y (ed.) *Advances in Cereal Science and Technology*, vol. 6, pp. 357–396. St. Paul, MN: American Association of Cereal Chemists; Singhal RS and Kulkarni PR (1988) Composition of the seeds of some *Amaranthus* species. *Journal of the Science of Food and Agriculture* 42(4): 325–331; Yue SX, Sun HL, and Tang DF (1993) *The Research and Development of Grain and Amaranth in China (in Chinese)*. Beijing: Chinese Agricultural Science and Technology Press; and Segura-Nieto M, Barba de la Rosa AP, and Paredes-López O (1994) Biochemistry of amaranth proteins. In: Paredes-López O (ed.) *Amaranth: Biology, Chemistry, and Technology*, pp. 75–106. Boca Raton, FL: CRC Press.

[c] $N \times 5.85$.
[d] $N \times 5.7$.
[e] $N \times 6.25$.

Table 4 shows that amylose makes up from 0% (waxy) to 34.3% of total starch in amaranth grain with the balance being the amylopectin, showing that there is considerable variation in amylose/amylopectin ratio among and within the *Amaranthus* species. Light-colored grains normally contain more starch (mean 69%) than dark-colored grains. Starches isolated from *A. hypochondriacus* genotypes contain the lowest amount of amylose (7.8%), whereas *A. retroflexus* genotypes have the highest amylose (34.3%). The average amylose content of 124 genotypes is 19.2%.

Amaranth starch granules come in polygonal, lenticular, circular, and elliptical shapes. Amaranth starch granules are extremely small, ranging from 0.8 to 2.5 μm in diameter. Comparatively, diameters of the granules in commercial starch range from 3–8 μm for rice starch to 15–100 μm for potato starch. Amaranth starch granule size and its size distribution are characteristics that influence the functional properties of starch.

Beijing: Chinese Agricultural Science and Technology Press; and Wu HX and Corke H (1999) Genetic diversity in physical properties of starch from a world collection of *Amaranthus*. *Cereal Chemistry* 76: 877–883.

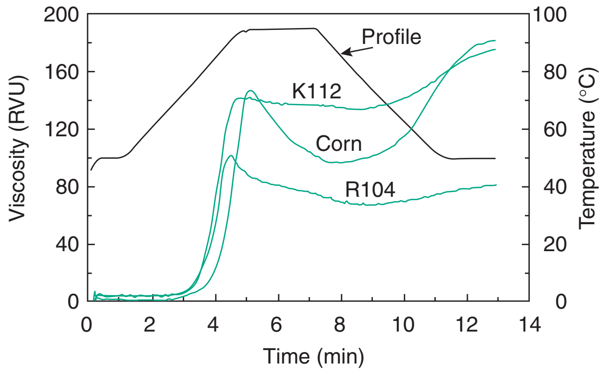

Figure 2 RVA pasting profiles of two *Amaranthus* genotypes (K112 and R104) compared with corn (Adapted from Wu HX, Yue SX, Sun HL, and Corke H (1995) Physical properties of starch from two genotypes of *Amaranthus cruentus* of agricultural significance in China. *Starch/Stärke* 47: 295–297 and Corke H, Wu HX, Yue SX, and Sun HL (1997) Developing specialty starches from new crops: a case study using grain amaranth. In: Campbell GM, Webb C, and McKee SL (eds.) *Cereals: Novel Uses and Processes*, pp. 91–102. NY: Plenum Press.)

Since the 1970s some interesting findings on physico-chemical and functional properties of amaranth starch have been reported, e.g., stable paste properties and a wide range of viscosity, resistance to shear thinning, and gelatinization temperatures. The focus of such research was restricted to very few *Amaranthus* species or genotypes, and sometimes gave contradictory results due to the genetic variation of the properties of amaranth starch. *A. hypochondriacus* starch had a higher amylograph viscosity, a higher gelatinization temperature, a lower swelling power, and a higher solubility than wheat starch. *A. paniculatus* (synonym: *A. cruentus*) starch had moderate swelling power, higher solubility, and lower pasting viscosity than foxtail millet starch. Compared to maize starch, *A. paniculatus* starch had a higher paste viscosity, lower paste clarity, and higher freeze/thaw stability.

A large number of *Amaranthus* germplasm (26 species) were introduced into China for evaluation of amaranth starch properties. Compared to the reference maize, rice, potato, and wheat starches, *Amaranthus* starch tended to have more stable paste, i.e., lower pasting viscosities (lower shear thinning and lower retrogradation), higher gelatinization temperature, and higher energy of enthalpy for gelatinization. Also, *Amaranthus* starch paste was more resistant to cold storage and had softer gel texture, lower changes of hardness, cohesiveness, modulus, and adhesiveness. Figure 2 displays the Rapid Visco Analyzer (RVA) pasting profiles of *Amaranthus* starch compared with maize starch. A wide range of variation was found in the several tested properties of starch among the *Amaranthus* species and among genotypes within the same species, suggesting that the wide genetic diversity necessitates specific choices for specific uses. Interestingly, it was observed that there were significant effects of environment on the tested properties of *Amaranthus* starch, indicating that starch of the same genotype might have different starch properties if grown in different locations. Additionally, obvious effects on pasting and rheological properties from genotypic, pH, and salt factors were found.

Recently, amaranth starch has attracted increasing attention because of its unusual properties. Possible product uses of amaranth starch, capitalizing on its small granule size, could include food thickeners, dusting powders for cosmetic as well as food uses, laundry starch, and even possible biodegradable plastics. The unique properties of *A. caudatus* starch, namely, its pasting properties and high susceptibility to amylase, might represent potential uses as food, feed, and fuel. *A. hypochondriacus* starch had relatively low gelatinization temperature and food freeze–thaw stability, indicating its use in gravies, sauces, and soups. *A. paniculatus* starch could be used in salad dressings and custard preparations. There were also reports on chemical modification (e.g., succinylation and hydroxypropylation) of amaranth starches and their properties.

Many studies demonstrated that starches isolated from many *Amaranthus* species could be used as good thickeners, stabilizers in salad dressing, canned food, sauce, frozen food, etc., because of their stable paste, low retrogradation, freeze–thaw resistance,

and heating and cooling resistance. Also, there has been a report that describes amaranth starch as behaving very poorly in breads and cakes from the standpoint of color and appearance, texture, and volume, probably because of its low amylose content. During starch application, it is worth paying attention to a fairly wide variation of amaranth starch properties among different species and genotypes.

Amaranth Protein

The second most abundant component of amaranth grains is protein. Based on the amino acid composition, amaranth seed protein is known to be of higher quality than most of the major cereal grains. The essential amino acid composition of amaranth grains from different *Amaranthus* species is summarized in Table 5. The lysine content is 2–3 times higher than that of the most common cereals, and sulfur amino acid content is also relatively high as compared with that of the most important legumes (pea, bean, soybeans, etc.). Table 5 also shows clear variation in amino acid composition among different species. Because amaranth protein has a better balance of the essential amino acids than in cereals and legumes, it scores higher than other seeds (e.g., wheat, barley, soybean, and maize) in the FAO/WHO Nutritionist's Protein Value Chart: a score of 100 is the ideal, whereas amaranth protein received the highest score of 75, compared to cow milk (score = 72), soybeans (68), and peanuts (52), indicating that its balance was closer to the optimum required in the human diet (FAO/WHO).

Seed proteins are generally classified into four types based on solubility: albumin, globulin, prolamin, and glutelin. Most studies on amaranth proteins suggested that albumin was the major fraction (48.9–65%), followed by glutelin (22.4–42.3%), globulin (13.7–18.1%), and prolamin (1.0–3.2%). However, there was variation in amaranth protein fractions because of protein extraction and fractionation procedures, and due to genetic variation. For instance, it was reported that the fractionated proteins from five different *Amaranthus* species averaged albumin (65%), globulin (17%), prolamin (11%), and glutelin (7%). Also, it was reported that the isolated proteins from *A. hypochondriacus* consisted of 46–49% albumin plus globulin, 3% prolamin, and 30–33% glutelin, and in another study of same species, similar percentages of albumin, globumin, prolamin, and glutelin were 51.0, 15.9, 2.0, and 31.1, respectively.

In the 1980s and 1990s, many researchers isolated major fractions (albumin, globulin, and glutelin) of proteins from main *Amaranthus* species and examined their biochemical and physico-chemical properties and molecular weights. Based on their measurements of its emulsion activity, foaming stability, and surface hydroscopicity, along with its relatively high heat stability, it was concluded that amaranth proteins could be useful as effective emulsifying and foaming agents. On the other hand, there were reports that *A. cruentus* and *A. hypochondriacus* protein fractions had poor emulsifying and foaming properties, limited water absorption, and good gel-foaming properties.

In the past several years, a series of studies on properties and utilization of amaranth protein have been carried out. It was found that protein concentrates made from amaranth grains of five genotypes exhibited better solubility, emulsification, and foaming properties than the commercially available soy proteins (Table 6). The effect of proteins on starch gelatinization and retrogradation was investigated using the hydrolyzed and native protein concentrates of amaranth. The results suggested that native proteins tend to be attracted towards the starch granule and contribute to regulation of swelling and amylose leaching during gelatinization, therefore resulting in a weaker starch gel. However, hydrolyzed proteins showed similar effect, but to a much lesser extent. Furthermore, amaranth protein concentrates were examined for direct application in certain food systems (wheat dough and noodle). It was found that the mixing properties of wheat flour were improved by the addition of the protein concentrates. Addition of protein concentrates to a noodle formulation also showed some positive influence on final product

Table 5 Essential amino acid composition of grains from three major *Amaranthus* species (g per 100 g protein)[a]

quality. A few amaranth protein concentrates were also evaluated as fillers for an emulsion-type meat product. Only one of the amaranth protein concentrates (genotype K112) gave some favorable results.

Amaranth Oil

Oil is another chemical component of much interest in amaranth grain, because it contains relatively higher levels of oil (5–8%) than cereal grains; moreover, there is a considerable amount of squalene in amaranth oil (~5%) compared with that in oils of cereals and other oil crops (0.01–0.4%) (Table 7).

Palmitic, oleic, and linoleic acids are the major fatty acids in amaranth oil, with the saturated/unsaturated fatty acid (S/U) ratios ranging from 0.12 to 0.50. Published data showed that the fatty acid profiles in amaranth oil from different species were as follows: palmitic (12–25%), oleic (19–35%), linoleic (25–62%), stearic (2–8.6%), and linolenic (0.3–2.2%) acid. The squalene levels range from 5% to 8% in *A. cruentus* oil. Lower amounts of squalene (2–5%) are tested in some *Amaranthus* species of West Africa. Other lipids in amaranth – such as triglycerides, sterols, methylsterols, terpenic and aliphatic alcohols, tocopherols, and hydrocarbons – have also been identified. Recent results indicated that the major fatty acids in amaranth oil from 11 *Amaranthus* genotypes included palmitic acid (19.1–23.4%), oleic acid (18.7–38.9%), and linoleic acid (36.7–55.9%), with the S/U ratios of 0.26–0.32. The squalene content in amaranth oils from 11 genotypes of four species ranges from 3.6% to 6.1% (Table 7). These reports reveal the significant variation in oil composition content among various species and genotypes.

Squalene is a biosynthetic precursor to all steroids. It is an important functional ingredient in skin cosmetics and also as an excellent computer-disk lubricant. It has been reported that the decreased risk for some cancers might be associated with squalene consumption, and the use of squalene alone is effective in decreasing serum cholesterol levels. The traditional source of squalene is from shark and whale liver oil. Estimates in 1994 place the world market at 1400 t $year^{-1}$. It is very expensive ($53 000 per ton). Amaranth oil will attract more attention as an alternative plant source of squalene because of its abundant squalene content, although efforts to further increase the level are necessary.

Squalene can be easily extracted from amaranth grain by simple vacuum distillation. Recently, work to screen genotypes containing a higher content of squalene in a wide range of *Amaranthus* species and to develop efficient large-scale separation technique has been conducted; a method was established to separate and purify squalene from amaranth oils. After saponification, squalene content increased from 4.2% to 43.3% in the unsaponifiables by the removal of the saponifiables. The unsaponifiables were fractionated by a chromatographic method to

obtain highly purified squalene. The final purity of squalene reached 94–98%.

However, amaranth oil occurs in very low levels and at higher cost than oils of peanut, olive, rapeseed, etc. Unless a specialty starch or protein could also be produced from the defatted meal, a substantial decrease in raw product cost will probably be required before amaranth oil goes commercial.

Amaranth Pigments

There has been an increasing trend toward replacement of synthetic colorants with natural pigments since the 1980s because of safety and health concerns. Red-colored vegetative tissues of *Amaranthus* plants contain a high concentration of betalain pigments and are often produced in high biomass (Table 8). They have attracted considerable interest as potential substitutes for the well-known betalains from beetroot (*Beta vulgaris*) which are extensively used in the food industry worldwide. In recent years, a comprehensive systematic study on amaranth pigments has covered field evaluation and selection of betalain-producing genotypes/species, extraction, identification and quantification of betalain components, determination and evaluation of properties and antioxidant activity, and pigment production and utilization in certain food systems.

Betalains are divided into two major structural groups, i.e., red-violet betacyanins and yellow betaxanthins. Amaranth pigments belong to betacyanins. They could be easily extracted with water or methanol. Sixteen kinds of betacyanins were isolated and characterized from plants in the Amaranthaceae. Figure 3 shows HPLC profile of amaranthine-type betacyanins and their molecular structures, which are predominant pigments in all *Amaranthus* species. Quantitative analysis data showed that the screened amaranth species/varieties yield higher betacyanin pigments than feasible in beetroot production.

Table 8 Pigment content and fresh weight of 12 genotypes from seven *Amaranthus* species[a]

Species	*Genotypes*	*Fresh weight of colored parts (kg ha^{-1})*[b]	*Total betalain content (mg per 100 g FW)*[c]
A. cruentus	12	56 390 ± 7225 *(Lv,In)*	42–199

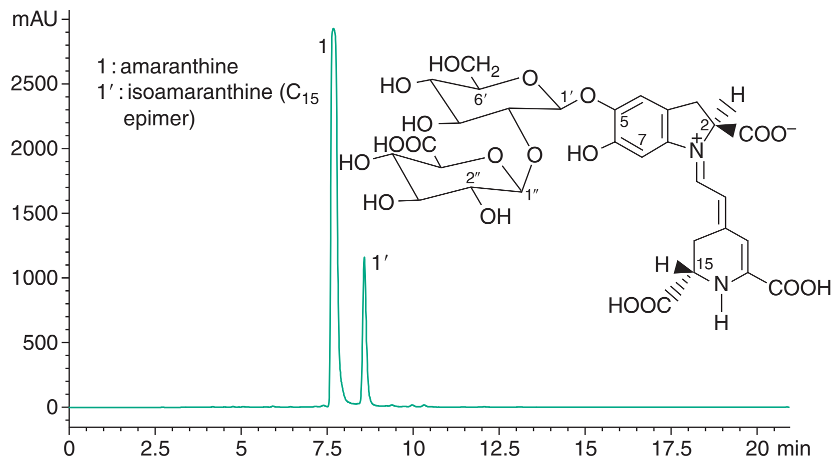

Figure 3 Structure and HPLC elution profile of amaranthine-type betacyanins from *A. tricolor*. The isomeric form (1′) is the C-15 epimer of corresponding betacyanin (not drawn).

Colorant properties and stability of the betacyanins are the key factors of pigment quality that directly influence their application in food systems. Assessment of color characteristics and stability of betacyanins from *Amaranthus* species showed that *Amaranthus* betacyanins exhibited bright red-violet color and favorable stability under selected conditions (pH 5–7 and temperature <14°C), as compared to red radish anthocyanins. Dried *Amaranthus* pigments had good storage stability ($t_{1/2}$ = 23.3 months) at room temperature. The presented data support the potential development and utilization of *Amaranthus* betacyanins as new natural colorants for use in the food industry, particularly for low-temperature uses.

Aqueous extracts of natural pigments are commonly unstable, and sensitive to storage environmental factors. Spray drying can significantly improve storage stability. *Amaranthus* betacyanin extracts were spray dried using a range of 10–25 DE maltodextrins as carrier and coating agents at different inlet/outlet air temperatures and various feed solid contents. The best-dried pigment powder made was superior to commercial red beet powder in terms of physical properties (**Table 9**). The results demonstrated the feasibility of production of spray-dried *Amaranthus* betacyanin extracts as a food-grade colorant.

Application of *Amaranthus* betacyanins in jelly, ice cream, and a model beverage was evaluated by comparison to commercial colorants (red radish anthocyanins and synthetic colorant FD&C Red#3). The results revealed the feasibility and potential of *Amaranthus* betacyanins for use in the model food systems at low temperature. *Amaranthus* betacyanins in the foods examined exhibited better color characteristics than red radish anthocyanins at the same levels, but were not as bright as FD&C Red#3. The betacyanins had color stability comparable to red radish and FD&C Red#3 at lower temperature (<14°C), and also similar color stability at 25°C, but not as stable as the two commercial colorants at higher temperature (37°C).

Additionally, all betalains isolated from plants in the Amaranthaceae exhibited strong antioxidant activity. To date there has been evidence suggesting that certain natural colorants as nutritional antioxidants in the diet may reduce the risk of some diseases. This gives the possibility of these betalains being used both as natural colorants and as potential natural antioxidants.

Food and Feed Utilization of Amaranth

Traditional foods are made from amaranth grains in many countries, e.g., "alegria" and "atole" in Mexico, "alboroto" in Guatemala, "bollos" in Peru, "Chapati" in Himalayas, "laddoos" in India, and "sattoo" in Nepal. These amaranth-based foods are still consumed today in various areas of the world. Modern food applications of amaranth grains include breakfast foods, infant/weaning food formulations, breads, pastas, flakes, drinks and beverages, etc. Currently available consumer food products include popped foods, baking mixes, malted flours, breakfast cereals, snacks, baked goods, and whole amaranth products. In China, a wide range of amaranth food products has been developed for retail sale. These include instant flour for beverages or porridge, packaged dried noodles, cakes, biscuits, and soy sauce made from brown-black amaranth and other grains (wheat, soybean). China has a wide diversity of traditional food products made from specialty grains, such as buckwheat, millets, sorghum, and legumes. By adapting products made from these, additional amaranth-based foods have been developed, such as composite flour instant noodles, distilled spirits, and vinegar. Furthermore, vegetable amaranth has been used as a traditional vegetable for several centuries in China. In sub-Saharan Africa and Central and Southern America, vegetable amaranth is also an important leafy vegetable, consumed as a cooked green vegetable, or used in soup.

Amaranth is a fast-growing, high-nitrogen, and high-biomass plant that can be used fresh or as silage for animal feed. Amaranth grain flour or powdered leaf meal can be used to make commercial pelletted or other compound feeds. Currently, feed application of

amaranth has been successful and popular in China and has played a role in developing Chinese animal husbandry. Amaranth feeds made from leaves, stems, panicles, and grains include green fodder, silage, leaf and seed-meal feed, pellet feed, etc. The evaluation of feed use has shown that amaranth feeds efficiently raise pigs, chickens, cattle, sheep, and fish to improve the quality and productivity of animal production. Chinese peasant households are accustomed to raise livestock and poultry, and nowadays in many areas amaranth is the main source of silage for household pig production. However, it is not widely used as feed in other countries.

In summary, amaranth possesses high yield potential, and high stress tolerance to drought, salinity, alkalinity, or acidic soil conditions. Its grains have attractive chemical composition, superior nutritive value, and some special functional properties. Its vegetative parts with high biomass can be used for animal feed. Its red-colored vegetative tissue with high level of betacyanins is a potential alternative source of well-known beetroot pigments (betalains). Amaranth has been attracting worldwide attention and will be a high-potential new crop with multiple uses. However, intense and continuous efforts are necessary in several aspects, such as amaranth breeding and field cultivation, relevant food/feed processing and development, product industrialization, marketing, etc.

ANIMAL FEED

J L Black, John L Black Consulting, Warrimoo, NSW, Australia

Introduction

Cereal grains are used widely as animal feed. Some plant species such as maize, sorghum, millet, triticale, and oats are grown predominantly for animal consumption, whereas others including wheat, barley, and rice are grown mainly for human consumption with grains not meeting market specifications frequently being fed to livestock. These latter grains are often small grains from screenings, broken grains, or damaged by weather. Cereal grains have a high content of starch relative to other ingredients used as animal feed such as forages or pulses and are offered to animals primarily as a source of readily available energy. Consequently, cereal grains are fed predominantly to intensively reared livestock such as dairy cows, feedlot cattle and sheep, pigs and poultry and may represent 60–80% of the ration, although they are also used for subsistence in times of poor pasture growth.

There is a large variation across cereal species, cultivars, individual grain samples, and animal types in the amount of energy available to animals from grains following ingestion. The extent of digestion of a grain by an animal depends on the adequacy of enzymes within the digestive tract capable of breaking specific chemical bonds in each grain component, the accessibility of the enzymes to the chemical components, and the time the enzymes and component are associated. Much of the variation between grains in energy availability can be explained by differences in gross chemical composition. However, other factors, particularly those that affect the accessibility of enzymes to specific grain components, can affect markedly the amount of energy in a grain that is available to different types of animals. Variation between animal types in the anatomy of the digestive tract and the digestive process has a substantial impact on the availability of energy and whether metabolic disorders are likely to result following grain consumption.

The variation between grains in energy availability is due in part to heritable characteristics, but much is due to the particular environmental conditions in which the grain was grown. From an understanding of the factors determining the availability of energy for each animal type, it is possible to identify grain characteristics that could be changed by plant breeding or specific processing methods to increase their energy value to animals. Although cereal grains provide amino acids, minerals, and vitamins to livestock, these nutrients are of minor importance in grains relative to other dietary ingredients and are not discussed.

Variation in the Energy Value of Cereal Grains

Definition of Available Energy and the Digestive Process

The energy available from digestion of a dietary ingredient is defined for most livestock as the amount of energy that is in chemical components digested and absorbed along the entire digestive tract from mouth to anus in mammals or cloaca in poultry. Available energy is determined by subtracting the energy in collected faeces from the energy consumed and is termed digestible energy (DE, $\mathrm{MJ\,kg^{-1}}$). However, in poultry available energy is defined as apparent metabolizable energy (AME, $\mathrm{MJ\,kg^{-1}}$), because the material excreted from the cloaca includes uric acid from the kidneys as well as faecal material.

The value of digested energy to an animal for metabolic processes varies widely depending on whether the digestive process is a result of animal secreted enzymes or enzymes of microbial origin. In the latter case, the digestive process is frequently termed microbial fermentation, which results in the conversion of dietary carbohydrates and proteins into growing microbes, volatile fatty acids, and other compounds with the release of methane, ammonia, and heat of fermentation. The fermentation process within the digestive tract can result in the loss of 10–20% of the energy in the digested dietary material, depending on the composition of the diet, conditions of fermentation, and microbes present.

Nevertheless, the fermentation process is important for animals, because microbial enzymes can cleave chemical bonds in plant material that cannot be broken by enzymes secreted by mammals and birds. Glucose units in grain compounds are commonly linked by α-(1–4), α-(1–6), or β-(1–4) glycosidic linkages. The α-(1–4) bonds, found predominantly in starch, can be hydrolyzed by animal digestive enzymes, whereas the β-(1–4) linkages, found in cellulose,

require microbial enzymes for cleavage. The α-(1–6) glycosidic linkages also restrict the action of animal amylases. Starch digested by animal enzymes is used more efficiently than that digested by microbial enzymes. However, the nonstarch polysaccharides in grains including cellulose and endosperm cell wall constituents – arabinoxylans, xylans, and (1–3, 1–4)-β-glucans – can be digested only by microbial enzymes. Although some energy is lost from the breakdown of these compounds during the fermentation process, 80–90% of the energy released is available to metabolic processes in the animal. The lignin content of grains, which consists of a range of phenolic polymers, is indigestible by animal enzymes and most intestinal microbes.

The anatomy of the digestive tract (Figure 1) and the digestive process varies widely between domestic livestock species. Feed consumed by ruminants is subjected to microbial fermentation within the rumen reticulum before it passes to the small intestines where animal enzymes are secreted. The starch in cereal grains is therefore first subjected to microbial digestion and, if degraded rapidly, can result in a significant increase in acid production and fall in rumen pH. Lactic acidosis caused by a rapid increase in the concentration of lactic acid and low pH disrupts the balance of microbes in the rumen, reduces digestion of other dietary constituents, particularly plant fiber, and can severely affect the health and productivity of the animals. The rate of starch fermentation in the rumen is influenced by characteristics of the grain and particle size. The latter depends on the extent of breakdown of grain during mastication and the effectiveness and type of grain processing. Sheep masticate grains more thoroughly than cattle and often grains are not processed before feeding to sheep, whereas cereal grains are frequently processed before being fed to cattle.

Although horses and pigs do not have a compartment like the rumen reticulum within the stomach for the fermentation of feed, the hind-gut contains a large microbial population which digests much of the nonstarch polysaccharide component of their diet. The starch component of cereal grains is first subjected to degradation by the animal secreted enzymes. However, if a large quantity of starch passes through the small intestines undigested, it is fermented in the hind-gut and can cause laminitis in horses through a lowering of pH and an increase in the susceptibility of pigs to enteric diseases such as swine dysentery and *Escherichia coli* scours. Pigs masticate their feed poorly and unless the grain is processed before ingestion, large quantities of starch can be fermented in the hind-gut. Poultry do not have a significant microbial population within the digestive tract and there is insignificant digestion of the nonstarch polysaccharide components in grain. However, poultry have a gizzard within their digestive tract, and the intense muscular contractions of this organ are extremely effective for physically breaking the grain into small particles and disrupting the integrity of the endosperm cell walls.

Variation in Available Energy between Grains and Animal Types

Examples of published variation in the available energy content of cereal grain species for poultry

Table 1 Variation in published values for the available energy content of cereal grains for poultry and pigs[a]

Cereal grain	*Poultry AME*[b] *(MJ kg^{-1} DM*[c]*)*	*Pigs DE*[d] *(MJ kg^{-1} DM*[c]*)*
Wheat	10.3–15.9	13.3–17.0
Barley	10.4–13.5	11.7–16.0
Triticale	8.6–15.2	14.8–16.0
Sorghum	13.5–17.7	15.8–17.4
Maize	15.5–17.0	
Oats	10.5–12.4	

[a]Constructed from (1) Hughes and Choct (1999) Premium grains for livestock. *Australian Journal of Agricultural Research* 50(5) and (2) van Barneveld (1999) Chemical and physical characteristics of grain related to variability in energy and amino acid availability in pigs: a review. *Australian Journal of Agricultural Research* 50: 667–688.
[b]Apparent metabolizable energy.
[c]Dry matter.
[d]Digestible energy.

and pigs are shown in Table 1. The difference between values in AME for poultry of 3–6 MJ kg^{-1} DM for wheat, barley, triticale, and sorghum would have a large impact on productivity, whereas the difference of 1.5–2 MJ kg^{-1} DM for maize and oats is less, but still important for commercial animal production. A similar difference between values in DE was observed for wheat and barley fed to pigs, but the difference for triticale and sorghum was less than reported for poultry. The results do not cover the same grains fed to both pigs and poultry, and the range in available energy values reported would include differences in experimental techniques between laboratories. Nevertheless, a difference of only 0.5 MJ kg^{-1} DM in the energy content of cereal grains can have a significant effect on animal productivity, efficiency of feed use, and profitability of intensive animal enterprises.

A comparison of the available energy content of the same grain samples when fed to pigs, broiler chickens, and laying hens is shown in Figure 2. Other examples of the available energy content of the same grain sample offered to sheep, cattle, pigs, broiler chickens, and laying hens are shown in Table 2. The table employs the same grain species, cultivar, or type as used in the experiments, but the available energy values observed often are more closely related to the actual sample and the growing conditions rather than to the species and cultivar description.

There were relatively small differences in the available energy content of some individual grain samples when compared across the animal types, but for other grains the differences were marked. Figure 2 shows that the available energy content of cereal grains for pigs and poultry generally followed a close relationship. More energy tended to be available to pigs than poultry for barley and wheat samples. For most grains there were only

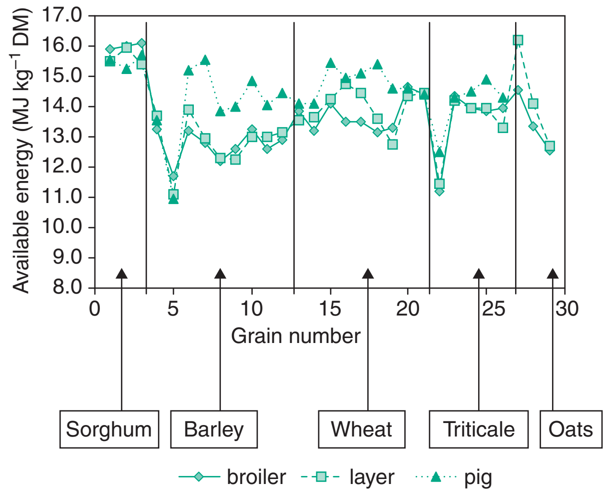

Figure 2 Available energy content of grains (MJ kg^{-1} DM) as apparent metabolizable energy for poultry and as digestible energy for pigs offered the same grains. (Updated from Black JL (2000) *Proceedings of the Australian Poultry Science Symposium* 13: 22–29.)

Table 2 Available energy content of grains[a] (MJ kg^{-1} DM) fed across animal species as digestible energy for sheep, cattle, and pigs and as apparent metabolizable energy for poultry[b]

Grain	*Sheep*	*Cattle*	*Pigs*	*Broilers*	*Layers*

small differences in the available energy content of grains between broiler chickens and laying hens. The most striking difference was for a naked oat sample where the value was 16.2 MJ kg^{-1} DM for laying hens and only 14.6 MJ kg^{-1} DM for broiler chickens. The barley and wheat samples in the first section of Table 2 had a higher energy content for pigs than the other animal species. However, these differences were not apparent for the Arapilies and Reinette barley samples in the second section of Table 2. The

available energy content of the barley samples examined ranged from 11.5 to 15.5 MJ kg^{-1} DM for sheep, but only from 11.7 to 13.2 MJ kg^{-1} DM for broiler chickens. The available energy value for the naked, waxy barley sample, Merlin, was high for both sheep and pigs, lower for layers, and substantially lower for broilers. Merlin was not fed to cattle.

The most striking differences between the animal types were for sorghum where the energy content for cattle of nonwaxy sorghum was only 65% of that for broiler chickens. The digestible energy content for cattle of a waxy isoline was substantially greater than that of the normal isoline (13.7 MJ kg^{-1} DM compared with 10.1 MJ kg^{-1} DM), but was only 86% of the value for broiler chickens. This difference in energy content between waxy and nonwaxy isolines of sorghum was not apparent for any other animal species examined. In addition, for all animal types except cattle, the available energy content of sorghum was higher than that of the other cereal grains. However, there are important differences between pigs and poultry in the site of sorghum digestion. The mean ratio of energy digestion to the end of the small intestines (ileal DE) to digestion along the entire digestive tract was 0.87 for pigs and 0.99 for broiler chickens. This result shows that ~13% of the energy digestion from sorghum in pigs is through microbial fermentation and indicates that broiler chickens obtain significantly more energy for metabolism from sorghum than pigs.

Large variation has been observed in the digestibility of oat grains when fed to sheep and cattle. The variation in digestibility of whole oat grains suspended in a nylon bag in the rumen of cattle for 48 h (*in sacco* digestibility) or fed to growing cattle is shown in Table 3. The table shows also an indication of the lignin content of the hulls (lignin score – higher values represent higher lignin content) and growth rate of cattle. There was an extremely wide variation between the samples in digestibility and the performance of animals consuming the different oat grain samples. The oat samples containing high lignin contents had lower digestibility and resulted in slower growth rates than those with low lignin contents.

Storage of grain, particularly wheat, has been shown to significantly improve the AME content of some grain samples, but not others, for broiler chickens. Table 4 shows the AME values for six wheat samples at 1 and 4 months after harvest and the viscosity of water-soluble extract from the grains. Similar studies with wheat fed to pigs show that there is little effect of storage on the energy value of wheat for these animals.

The examples of available energy content of grains for different animal types provided above indicate that most grains with low-energy availability for one animal type will also have low-energy availability for other animal types. Similarly, most grains with high-energy availability for one animal type will have high availability for other animal types. However, some specific grain species or grain samples differ widely in their energy value between and within animal types. These observed differences between individual grains and animal types in available energy content of cereal grains illustrate the importance of being able to understand the reasons for the differences and to identify rapidly, the nutritional value of an individual grain sample.

Reasons for Differences in Available Energy between Grains

To identify the reasons for the differences in the available energy content of grains between animal types and between grains within an animal type, it is necessary to understand the critical steps in the digestion

process. The extent of grain digestion by animals depends on the availability of enzymes capable of breaking the specific chemical bonds of each grain component, the ability of the enzymes to come in contact with the bonds, and the length of time the enzymes are in association with the substrates. The differences between animal species in terms of the availability of enzymes and the role of microbial fermentation in the digestion of nonstarch polysaccharides have been discussed, which also form the reason why wheat and barley samples have a higher energy availability in ruminants and pigs than in poultry. The inability of animal secreted enzymes to degrade endosperm cell wall components is of major importance for the nonruminant species. In addition, there appear to be some differences between animal species in the concentration or effectiveness of secreted enzymes for digesting specific components of cereal grains.

The accessibility of an enzyme to a grain component can be affected by particle size and surface area, physical barriers like cell walls or chemical barriers such as the tight helical structure of amylose chains, hydrophobic properties of lipid molecules, or the sequence of amino acids within proteins. The latter affects protein digestibility and may influence the accessibility of enzymes to other substrates within the grain. The rate of passage of digesta through the digestive tract can affect the time enzymes are in association with the grain components and thereby alter the extent of digestion. The main factors that are expected to contribute to differences in the energy value of cereal grains for livestock are discussed.

Gross Chemical Composition of the Grain

The amount of energy available to an animal from a grain depends largely on the relative proportions of each chemical constituent because of differences in the extent of digestion or in the energy content of the constituent. There is a general positive relationship with starch content and negative relationship with fiber content of cereal grains and energy availability for all animal types. Relationships for sheep and broiler chickens are shown in Figure 3. Although the negative influence of fiber, cellulose, and nonstarch polysaccharides is less for ruminants than pigs and less for pigs than poultry, increasing fiber and lignin content of grains reduces the availability of energy from grains in ruminants. A clear negative relationship is presented in Table 3 between the lignin content of oat grains and digestibility in cattle. Lignin binds covalently to plant cell wall polysaccharides and proteins rendering them less accessible to digestive enzymes and reducing their digestibility.

The high energy availability for the naked oat sample for laying hens shown in Table 2 is due to the high proportion of lipid and its higher energy content than other grain components. However, the energy available to broiler chickens from the same oat sample was 1.6 $\mathrm{MJ\,kg^{-1}}$ DM lower than for layers, because of a lower concentration of lipase enzymes and lower digestion of the lipid in the younger birds.

Although gross chemical composition of a grain and the digestive system are major determinants of available energy content of cereal grains for animals, other factors contribute to the variation observed between grain samples and animal types. Much of the variation that cannot be explained by chemical composition and digestive system relates to physical barriers limiting the enzyme contact with chemical components of the grain.

Endosperm Cell-Wall Composition, Thickness, and Integrity

Endosperm cell walls are composed of a cellulose skeleton impregnated with soluble and insoluble arabinoxylans and β-glucans. Although these cell walls have little effect on the accessibility of starch from cereal grains for ruminants, they can reduce the contact of amylolytic enzymes with starch granules and lower-energy availability for nonruminant animals by acting either as a physical barrier or by increasing the viscosity of the digesta.

Endosperm cell walls act more as a physical barrier for pigs than for poultry. Grains eaten by birds are subjected to intense grinding in the gizzard, and most endosperm cell walls are ruptured. However, pigs appear to rupture few cells during mastication, and the availability of energy from cereal grains is increased substantially by fine grinding. Fine grinding breaks the integrity of the cell walls and exposes the starch to amyolytic enzymes. However, fine grinding does not increase the availability of energy from cereal grains for poultry, because the cells are broken during normal movement through the digestive tract. Although there is little scientific proof, it is logical to presume that cereal grains with large endosperm cells will require less processing for pigs than grains with small cells, because more starch would be available through the disruption of the same number of cell walls.

There is strong evidence that the availability of energy from cereal grains in poultry is inversely related to the content of soluble nonstarch polysaccharides comprising largely arabinoxylans, xylans, and β-glucans. A linear decline has been observed in broiler AME values from 17.5 $\mathrm{MJ\,kg^{-1}}$ DM for rice to 11 $\mathrm{MJ\,kg^{-1}}$ DM for rye with increasing nonstarch

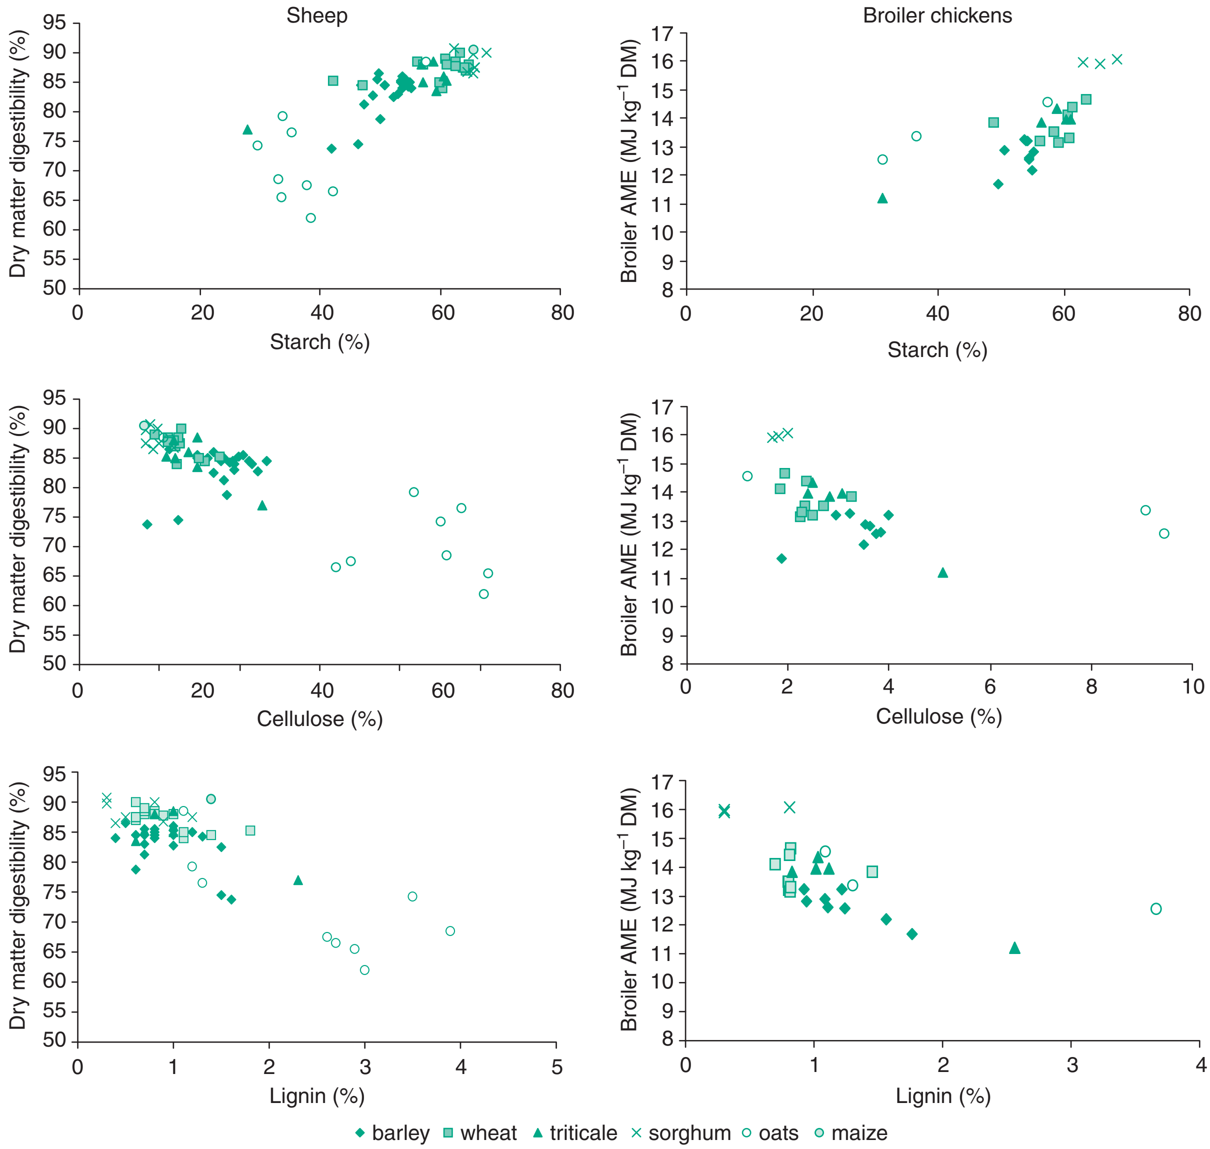

Figure 3 Relationships between starch, cellulose, and lignin content of cereal grains and dry matter digestibility (%) in sheep and apparent metabolizable energy content (MJ kg^{-1} DM) in broiler chickens. (Unpublished results from Flinn PC, van Barneveld RJ, and Hughes RJ.)

polysaccharide content of the grain (Figure 4). Soluble nonstarch polysaccharide compounds are believed to increase the viscosity of digesta, reduce the diffusion of digestive enzymes through the digesta, and reduce the rate of substrate digestion.

Chain length of soluble nonstarch polysaccharide polymers appears to be more important for reducing AME of wheat for broilers than is the total soluble nonstarch polysaccharide content, because of the greater increase in digesta viscosity, which reduces the digestion of starch, amino acids, and fatty acids. The addition of long chain pentosans to a sorghum-based diet fed to broiler chickens significantly reduced the availability of energy. However, if the pentosans were first hydrolyzed to pentoses using arabinoxylanases and glucanases, viscosity of the digesta declines and the availability of energy was restored (Table 5).

Enzymes that degrade soluble nonstarch polysaccharide compounds are now regularly added to diets for poultry to reduce the viscosity of digesta and increase the access of enzymes to dietary substrates within the small intestines. The addition of nonstarch polysaccharide degrading enzymes to the Merlin barley sample listed in Table 2 increased the AME value for broiler chickens from 12.6 to 14.6 MJ kg^{-1} DM. The observed increase in the AME content of cereal grains following several months storage after harvest

is believed to be due to a reduction in the chain length of soluble nonstarch polysaccharides within the grain through the activity of endogenous grain enzymes.

Soluble nonstarch polysaccharides have a greater impact on energy availability for poultry than for pigs because of inherent differences between the species in both the normal viscosity of digesta and the transit time through the small intestines. The dry matter content of digesta is 16–20% in poultry compared with 7–10% in pigs and corresponding rates of passage of digesta through the small intestines are 2–4 h for poultry and 12–24 h for pigs. The fast transit time of digesta in poultry decreases the time digestive enzymes and grain components are in contact compared with pigs.

Protein Matrix Surrounding Starch Granules

Starch granules in the endosperm of cereal grains are inserted to varying degrees in a protein matrix. In some grains such as sorghum, the protein matrix and embedded protein bodies can form a contiguous layer around individual starch granules. Figure 5 shows the protein matrix surrounding each of the starch granules of a sorghum grain when some starch granules were dislodged following soaking prior to preparation for microscopic examination.

The proteins surrounding the starch granules must be degraded to fully expose the starch to amylases. The protein matrix surrounding the starch granules in sorghum grain contains a high concentration of α-, β-, and γ-kafirins. These proteins contain increasing amounts of cysteine and methionine as they progress from the α- to γ-types and are rich in disulfide bonds that are resistant to cleavage by some enzymes. There is strong evidence that the low availability of energy from sorghum grain for cattle is due to the inaccessibility of amylolytic enzymes to the starch granules encapsulated by the protein matrix. Waxy sorghum grains appear to have a lower proportion of γ-kafirins than normal cultivars. The marked difference in digestion of sorghum starch by cattle compared with pigs and poultry is most probably due to differences in the capacity of proteases from the different animal species to degrade the high disulfide bond proteins in the matrix surrounding the starch granules. There is also likely to be differences between animal species in the concentration of these enzymes within the small intestines, which favors the degradation of the matrix proteins by poultry and pigs.

The degree of starch granule encapsulation, amino acid composition of the protein matrix, nature of proteases, and the presence of anti-nutritional factors such as tannins and trypsin inhibitors will affect starch digestion. Many earlier cultivars of sorghum were high in condensed tannins, which bound to digestive enzymes. There is evidence that the presence of the protein matrix may affect the extent of starch digestion in maize and barley grains when incubated with mixed microorganisms from the rumen of cattle. Incubation of ground barley with proteases has been shown to increase significantly the digestion of starch. It is probable that the susceptibility of the protein matrix to proteases within the digestive tract of animals varies between barley grain cultivars as has been shown for sorghum cultivars.

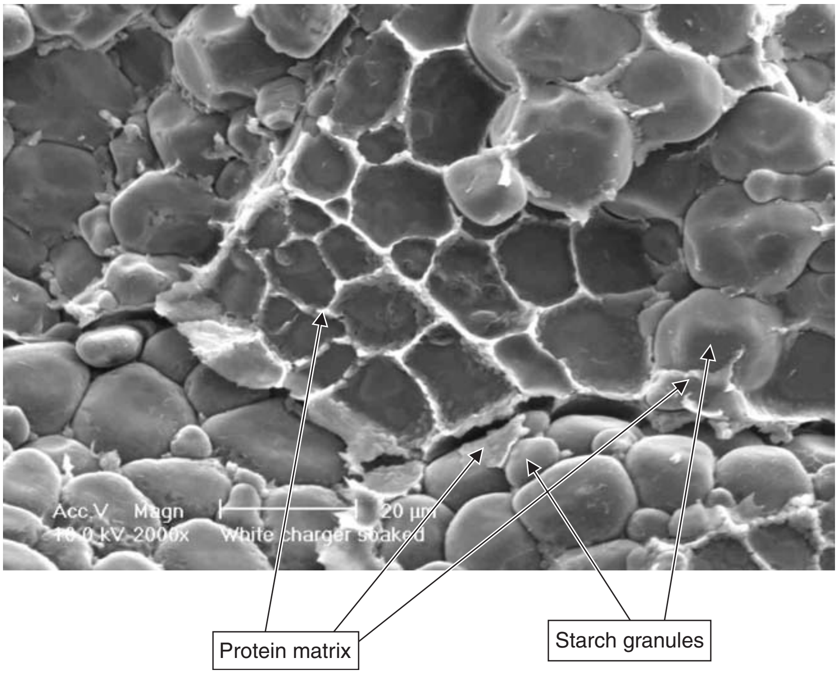

Figure 5 An electron micrograph of sorghum endosperm showing the protein matrix which encapsulates starch granules. (Unpublished results from Blakeney AB.)

Composition of Starch

Cereal starch is composed primarily of amylose and amylopectin. The tight helical structure of the long chains of glucose in the amylose molecule makes it less accessible to amylases than amylopectin with its branched α-(1–6) linkages. The α-(1–6) glucose branches provide a more open structure to the starch molecule, which increases the accessibility to amylolytic enzymes. Grains that contain starches with low proportions of amylose are translucent in appearance and are termed waxy grains. Starches with high proportions of amylopectin have lower gelatinization temperatures than high-amylose starches, and waxy grains produce harder, more durable stock pellets due to the greater ease of gelatinization.

The rate of digestion of isolated starch from waxy sorghum is faster than that for a nonwaxy isoline and is compared with the digestion of starch from wheat and maize in Table 6. These results confirm that the rate of digestion of isolated starch is increased as the amylose content declines. Experiments with pigs have produced a significantly higher digestibility in the small intestines of starch when amylopectin-rich barley (9 : 91, amylose : amylopectin) was compared with normal barley (30 : 70, amylose : amylopectin). Similarly, the digestibility of low-amylase maize in the small intestines of rats has been observed at 96% compared with 68% for high-amylose maize. The higher intrinsic rate of digestion of starch from waxy sorghum contributes to its higher rate of digestion, but the lower γ-kafirin content of the protein matrix is also an important factor for increasing the availability of energy in waxy sorghum for cattle.

Table 6 Gelatinization temperature and susceptibility to α-amylase digestion of starch isolated from several sorghum isolines, wheat, and maize

Grain	*Gelatinization temperature[a] (°C)*	*α-Amylase susceptibility[b] (mg digested)*	*α-Amylase susceptibility relative to maize (100)*
Sorghum			
Nonwaxy isoline	74.5	23.2	96
Waxy isoline	70.8	30.0	124

[b] 3 h digest with α-amylase of 1 g starch.
Unpublished results Blakeney AB.

Starch Granule Size

The size of starch granules in cereal grains varies widely from large A granules to small B granules. The surface area of the granules increases per unit of starch as the granule size decreases and exposes

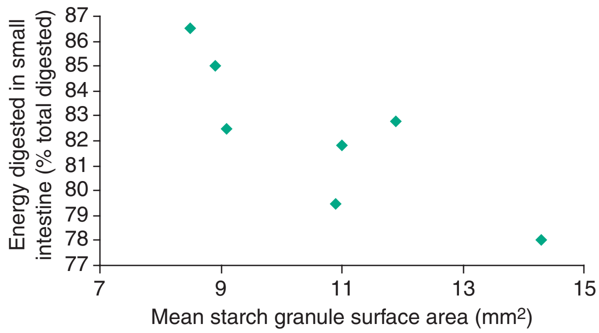

Figure 6 Relationship between the proportion of total energy digestion occurring in the small intestines of pigs and the average surface area of individual starch granules in wheat grain. (Unpublished results from Zarrinkalam M-R.)

a greater surface area for attachment of enzymes. The rate of digestion of cereal grains with small granules should be greater than for grains with a higher proportion of large granules, provided the small granules are not encapsulated within a protein matrix. There is evidence in pigs that increasing average granule size in wheat grain samples, as measured by average surface area of the granules, leads to a decrease in the proportion of energy digested in the small intestines (Figure 6). This result would be expected if the rate of digestion of grains with small starch granules was greater than of grains with larger granules.

Conclusions

The information presented suggests that the availability of energy from cereal grain varies widely between grain species, cultivars, and specific samples, and across animal types. An understanding of the reasons for these differences indicates that the energy value of grains could be improved by plant breeding and processing techniques. Clearly, an increase in the starch and decrease in the fiber content of cereal grains will increase energy availability for all animal species provided the grain compounds are accessible to digestive enzymes. A decrease in the lignin content of grains, particularly oat grain, would improve the availability of energy for ruminants. The availability of energy from cereal grains for pigs and poultry could be increased by breeding grains with thin endosperm cell walls and low-amylose starch. The digestibility of sorghum for cattle could be improved by breeding for a highly digestible protein matrix. Alternatively, the nutritional value of cereal grains could be increased by various processing techniques such as fine grinding for pigs and the addition of xylanase and glucanase enzymes to reduce the effect of cell wall constituents on digesta viscosity for poultry. Steam flaking, which gelatinizes the starch in sorghum and breaks the integrity of the protein matrix surrounding the starch granules, has proved to be an effective way of restoring the energy value of sorghum grain in cattle to a level similar to that for pigs.

BAKERIES

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia
C E Walker, Kansas State University, Manhattan, KS, USA

Introduction

Bread, in its many forms, is a staple food for mankind. It may be made in the home, one loaf at a time, or in a fully automated bakery, at a rate of tens of thousands of loaves per hour. Bread is baked and eaten in many different forms – thin or thick, soft or hard, sweet or plain, fresh or kept for many days (Figure 1). In some languages, the word for bread is the same as the word for food. Bread is practically the only food known almost universally around the world, from the most developed to the most primitive cultures, and it appears on the tables of the wealthiest and the poorest alike.

> Bread is a generous gift of nature, a food that can be replaced by no other. When we fall sick, our appetite for bread deserts us last of all; and the moment we recover the appetite, we have shown a symptom of recovery. Bread is suitable to every time of the day, every age of life, and every temperament. It improves other foods, is the father of good and bad digestion. Eaten with meat or other foods, it loses none of its delight. It is so perfectly adapted to men that we turn our hearts to it almost as soon as we are born and never tire of it to the hour of our death.
>
> Antoine Auguste Parmentier, Eighteenth Century French Nutritionist.

Historical Perspective

The origins of bread making are lost in prehistory when primitive man discovered that the seeds of some grasses could be crushed, mixed with water, and heated on the fire to make an appetizing food. Advances came from extending his ability to recognize the more appropriate seed species (primitive wheats), and later to cultivate them, thus avoiding the tedium of searching and gathering them. Later, advances involved the development of better recipes and procedures for mixing and baking. Some of these arts became the trade secrets of specialists – bakers – who produced bread in quantity, for sale to their

Figure 1 The square "sandwich" loaf, basic to the western diet.

Figure 2 The beehive oven was an essential part of the early bakery.

neighbors and beyond. Thus began the concept of the bakery – a place specifically designed for the efficient production of bread in quantity.

An early type of oven is illustrated in Figure 2, the so-called beehive oven. Shaped like an igloo as much as a beehive, this oven is timber-fueled, with a vent in the top for smoke to exit and to provide a draft. The stick at the right of the oven is a peel for placing dough pieces into the oven and for removing the baked bread.

The Baking Process

Today, all bread bakeries, small or large, follow the same basic procedures. The principal differences are in the scale (batch size) and the degree of mechanization and automation. Total processing time from the mixer to the consumer for commercial pan breads can be as little as 1 h or up to more than 8 h, depending upon the process. These basic procedures carried out in the bakery are set out in Figure 3. The steps involved (1–12) are described in detail below.

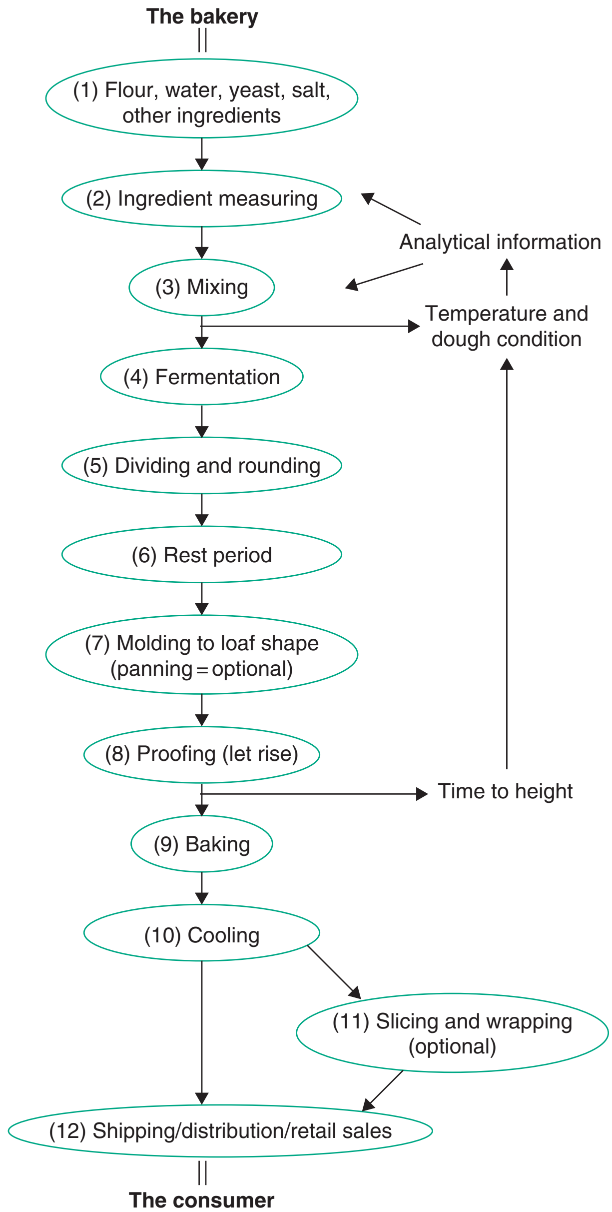

Figure 3 The basic procedures carried out in the bakery.

1. The most basic bread contains only flour, water, yeast (or a natural sour-dough starter), and salt. Its demand for use in bread and meat preservation caused salt to be one of the first items traded in antiquity.
2. Ingredients must be stored carefully and measured accurately if the product is to be consistent. Home and small retail bakers may measure by volume, but large bakeries measure by weight, often with scales that automatically weigh and add ingredients to the mixer.
3. The dough is mixed until it is homogeneous and "developed," meaning that it is smooth and elastic and able to hold the gas formed during fermentation and baking. Large batch mixers may hold 1 t or more of dough (Figure 4), but the home baker may mix just enough for one loaf by hand.

   Chemical and physical test information on the dough is provided to the baker, which helps in adjusting the process for the particular formula and for the natural variation in ingredients. The dough temperature is monitored, and information on its characteristics is fed back to adjust the next batch.
4. Fermentation typically takes ~1–4 h, though some "short time" processes take much less. The

Figure 4 A horizontal dough mixer used in a commercial bakery.

Sponge-and-Dough process involves mixing and fermentation, followed by the addition of more flour and ingredients; thereafter mixing resumes.

5. The dough is divided into smaller pieces, taking into account the amount of weight loss (~10%) that will occur during baking, to get the final loaf weight. Dividing typically occurs at ~100 loaves per minute in a commercial bakery, with many modern production lines now approaching 200 loaves per minute. A boutique bakery, on the other hand, may make fewer than 100 loaves per day.

6–7. After the dough relaxes for a few minutes, it is "molded," or shaped into loaves, usually by flattening out into a disk, then rolling into a cylinder before being placed into a pan for common round-top or square sandwich bread.

8. The dough is allowed to rise, or "proof" to the desired height for ~1 h under moist and humid conditions. The yeast generates additional gas by fermenting the natural and added sugars into carbon dioxide and alcohol.

9. Baking can take less than 2 min at very high temperatures for thin "flat breads," or up to half an hour at moderate temperatures for pan breads (Figure 5). A few very large, dense, hearth bread loaves may take several hours and bake very slowly. The loaf's interior temperature typically reaches ~95–98°C.

Figure 5 Baked bread emerging from a traveling oven. (Reproduced with permission of BRI-Australia Ltd.)

10–11. After the bread is baked, it is usually cooled as quickly as possible to below 40°C inside before it is sliced and packaged. If it is too warm, it will "gum" the slicer bands and tear the bread. If it is bagged too warm, condensation forms in the package and mold spots form. The slicing and bagging operations are most prone to mechanical difficulties and to product losses.

12. Distribution can be as simple as placing the bread on a table or rack in front of the bakery where the walk-by customer purchases it unwrapped and still warm. Alternatively, it can involve overnight truckload shipments to distant warehouses and distribution facilities before reaching the retail store where shoppers buy it after it is anywhere from 1 day to 1 week old.

Home Baking

The concept of the commercial bakery has never replaced the practice of bread making at home. Irrespective of time in history or of social status, there is an irresistible attraction to the aroma of yeasted bread baking in the home kitchen and the taste of freshly baked bread, straight from the oven. In today's westernized society, the traditional art of baking yeasted bread in the home may be lost to some extent, being replaced by the baking of chemically leavened cakes and cookies, with yeasted bread being bought at the

supermarket. These changes are presumably due to the more complex procedures involved in the production of yeasted breads.

However, today's obsession with consumer goods has partly solved these problems with the provision of the baking machine, a "high-tech" computerized appliance that performs the three major steps of baking in the one unit, namely, mixing, proofing, and baking. These appliances were developed initially in Japan in the 1980s, in response to its attraction to the relatively new food, leavened pan bread, and the liking for hot, fresh bread in the home, especially at breakfast time.

The use of these baking machines has since spread worldwide. The baked product is appetizing while hot, but in general it is technically inferior to the quality of bread from a commercial bakery or even that produced by a skilled home baker. It has a relatively coarse crumb texture (due to inadequate development of the dough), less flavor and aroma (due to a short fermentation stage), and stales relatively quickly (due to the general use of a "lean" formula, lacking sugar and emulsifier, and a lower protein flour). It is thus unlikely that home baking will replace the manufacture of yeasted bread from a commercial bakery; nevertheless, the kitchen still has a significant place in the bakery story.

Bakeries in Western Societies

The Large Plant Bakery

The plant bakery is at the opposite extreme, compared to the home kitchen. Technological advances in baking have led to the development of very large bakeries, in which bread of uniform type and quality is mass produced using automatic control and uniform ingredients by expert staff with a minimum of staff numbers. There would normally be no sales at the bakery, but all baked product would be transported over a wide area to retail outlets, mainly supermarkets (*see* **Oven Technologies**).

Production in these large bakeries mainly involves sandwich loaves ("Pullman" loaves of square cross-section baked in lidded pans), with the potential to put out more than 10 000 loaves per hour. "Round-top" loaves might also be produced in plant bakeries, but there is a very limited variety of bread types. A second class of bread type from plant bakeries is the bun or dinner roll, and the rate of their production might be as high as 100 000 units per hour. Due to the need for extensive transport of the bread, a long shelf life is essential, and sophisticated packaging is needed.

Features of the plant bakery include the following:

- Computerized control of all stages of the baking process, including the prediction of consumer needs and scheduling the production volume for the day. The bakeries may operate 5 or 7 days per week.
- Very large bulk-storage bins for flour delivered from mills in bulk by road or rail (*see* **Wheat**: Dry Milling).
- Uniform quality properties for flour specifications (*see* **Wheat**: Dough Rheology).
- Pneumatic movement of flour and other ingredients around the bakery, thus avoiding manual handling and avoiding dust hazards.
- Filtration and temperature regulation of water used in dough mixing.
- Large mixing equipment, each mixer frequently making more than 1000 kg of dough (Figure 4).
- High-speed dough dividing and forming equipment, operating totally "hands free," with very narrow weight control.
- Automatic proofing cabinets that control the temperature and humidity; so the dough rises at the correct rate and is ready for the oven at the right time.
- Large traveling ovens to accommodate many loaves in a continuous process of baking (Figure 5) (*see* **Oven Technologies**).
- Regulation of oven temperatures, humidity, heat transfer rate, and speed to ensure uniform baking of all loaves.
- Automated facilities for the cooling, slicing, and packaging of loaves.
- Automated palletizing and loading of the delivery trucks.

This type of large bakery is most common in major centers of population in westernized countries – particularly North America, Europe, Australia, and New Zealand – and is characterized by stiff competition and a very low profit margin. France may be an exception, with a continuing preference for the smaller trade bakery, providing freshly baked bread to a local neighborhood.

The Independent "Scratch" Bakery

Like the French model of a local-neighborhood bakery, this is the traditional type of bakery, with one or a few skilled bakers making a wide range of bread types for sale on-site on a scale much smaller than that of the plant bakery. Bread is made "from scratch," i.e., all basic ingredients are incorporated in the bakery, as distinct from recent developments such as the "in-store" bakery (see below) where only the final stages of baking are performed. This type of bakery is often a family business catering for local needs and parochial preferences for bread types. Some "ethnic" bread types are still made in those

bakeries located in neighborhoods with many people from a common ancestry or country. It thus provides a valuable local resource, even a local meeting place, but it may be much less efficient than the plant bakery in terms of the production cost per unit. In recent decades, there has been a loss of this type of bakery, in some cases because the operators of plant bakeries have bought them out in order to expand their distribution network. In North America, the few remaining small local bakeries often produce principally cakes and pastries rather than the low-margin white pan bread. The majority of the 1200 British in-store bakeries (in supermarkets) are based on scratch production – not frozen dough or bake-off. Some other European countries have similar high numbers of scratch in-store bakeries (e.g., France, Hungary, and Portugal).

Hot-Bread Shops

This type of modest-sized operation has reappeared in recent decades in the form of the franchised "hot-bread shop," often located in shopping centers. In this type of bakery, all goods are baked within the bread shop for direct sale at the shop-front. In general, recipes and equipment are standardized. Some products might be produced "from scratch," but in many cases the earlier stages of production might be short cut, for example, by the use of bakery premixes containing all ingredients so that the main addition is water before mixing. In such bakeries, only a modest level of skill may be needed on the part of the bakery staff, thereby reducing costs. Nevertheless, a wide range of goods may be produced, including many "fancy" types of bread, sweet pastries, and filled doughs such as pies.

In-Store Bakeries

A further innovation of recent decades involves "taking the bakery to the people," namely, into the supermarket. This concept involves performing the last stage of the process, the baking step, within the supermarket so that the baked products are presented freshly baked for immediate sale. In this case, relatively unskilled staff can be used to load parbaked or frozen dough pieces into the oven for baking (rack- or reel-type oven) under prespecified conditions (*see* **Oven Technologies**). Although skill requirements may be modest, a range of bread types can be offered by the in-store bakery, thereby satisfying local demands.

The critical contribution to the success of the in-store bakery is the supply of frozen doughs or parbaked foods. These are produced at a centrally located "commissary bakery" and may be distributed relatively long distances. The commissary bakery may be a large plant bakery with automated facilities to take the baking process through to either the proof stage (before freezing) or the partly baked stage as parbaked (before refrigeration or freezing and transport). Recent trends favor the parbaked product for this concept. It can be stored and transported at room temperature for up to ~7 days, though some bakers claim shelf life of up to 2 weeks. Longer storage requires cooling or freezing to extend the shelf life of frozen dough to ~3 weeks and of parbaked dough up to several months if properly packaged and deep-frozen.

Frozen dough pieces are sometimes stored for much longer but the freezing process damages both the yeast and the gluten quality, so that higher levels of gluten must be used, together with special yeast strains (*see* **Gluten and Modified Gluten**). There have been some attempts to sell the frozen dough pieces directly to the homemaker, but a substantial amount of time is still required to properly thaw, proof (raise), and bake the dough. As a result, the use of frozen dough has never reached predicted levels in direct home sales. However, certain institutional applications, such as frozen pizza crust disks, have been very popular in some niche markets where, even when some skilled staff are available, they can save on the mixing and forming stages with their long lead times.

Old-World Bakeries

Bakery operations in the Middle East, Asia, and Latin America are generally on a small scale, catering for the local community, and producing baked goods that may once have been regarded as "exotic" by westerners. Labor and skill input is considerable, sales are on-site, and there is little need for packaging or for extensive transportation of the product.

The range of products is unlikely to include much of the western-style leavened loaf, but its popularity is increasing in these regions. More likely, these bakeries produce traditional breads suited to the local demand. In the Middle East, this includes various types of flat breads (Figure 6). Some of these are pocket breads that open in two layers for the insertion of pulses or other fillings. Thicker flat breads are popular in Turkey, North Africa, and India. Baked at very high temperatures, they have a very coarse, open, texture with a thick crust and are often "decorated" with the baker's finger marks on the top.

Tortillas were once considered to be "ethnic" breads (*see* **Tortillas**). With the growth of the Hispanic population in North America, however, they

Figure 6 A bakery in which Arabic flat breads are produced.

are now widely available and their production is switching from small artisan bakeries to large mechanized high-speed production. Hispanic types are speckled with dark brown spots and an irregular surface. Chinese preferences are for tortillas to be very white and smooth. Both types are used as wraps for filling in the center, as for a “Taco” or “Peking Duck.”

A number of small “boutique” bakeries have begun to appear in some areas. They tend to use very limited equipment to produce a small (and expensive) product, baked by residual heat in preheated heavy masonry ovens derived from the ancient “beehive” designs (Figure 2).

Specialized Baked Goods

Beyond the scope of what we would normally class as “bread” in its widest sense, there is a wide range of specialized bakery products. Many of them are sweet but some are savory, some are yeast leavened, but others are chemically leavened. The list includes foods such as cinnamon rolls, pretzels, doughnuts, snack foods, bagels, many types of cookies and crackers, cakes, and pastries. Bakeries differ considerably depending on the procedures and equipment needed for this diverse array of foods.

Some of these such as crackers and cookies are produced in vast quantities on very large, high-speed, automated ovens, whereas most of them individually involve small product runs. An outstanding example in the high-speed class is given by the many types of cookies and crackers made by Nabisco, making it the largest baking company in the USA, yet the company produces no bread.

Future Perspective

The future is likely to see the spread of larger plant-type bakeries into the centers of population in countries where traditional bakeries have always been the norm. This transition will involve the adaptation of automation and mechanization to bread types that have not previously been produced in such quantities and uniformity. Nevertheless, history has shown that the “bottom line” that determines the success or otherwise of any such innovation is the reaction of the consumer. It is the common person who buys the bread, selecting the source and type of their choosing, that ultimately determines the fate of any bakery.

Genetics and Breeding

J G Kling and P M Hayes, Oregon State University, Corvallis, OR, USA
S E Ullrich, Washington State University, Pullman, WA, USA

Introduction

Knowledge about barley genetics is expanding at a rapid rate, as molecular and information technologies provide increasingly detailed information about gene structure and function. The purpose of this article is to give an overview of the subject area, with references to recent reviews and online databanks that provide in-depth coverage of specific topics. The discussion will focus on traits and methodologies that have the greatest significance for applied breeding programs.

Barley (*Hordeum vulgare* L.) is one of the oldest domesticated crops, and is expected to have originated in the Fertile Crescent region of the Near East around 8000 BC. It has been used both as food and as a principal ingredient in fermented beverages since ancient times. Today, about two-thirds of the annual world production of 136 million metric tons (Mt) is used for animal feed (FAOSTAT). Among the cereal crops, barley ranks fourth in production after wheat, rice, and corn.

Cultivated barley is one of 31 *Hordeum* species, belonging to the tribe Triticeae, in the grass family (Poaceae). It is an annual, self-pollinating, diploid species with $2n = 14$ chromosomes. The relative simplicity of the genetic system and diversity of the species make it an ideal organism for genetic studies and breeding efforts. Currently the wild ancestor of barley (*H. vulgare* subsp. *spontaneum*) is expected to be a subspecies of cultivated barley, and cultivated barley is classified in the subspecies *vulgare*. Wild barley has a brittle rachis and occurs only in the two-row

form. Cultivated barley has a nonbrittle rachis and may be the two-row or the six-row form. *H. vulgare* subsp. *spontaneum* may be a transitional form between the true progenitor of barley and the cultivated species.

Morphological Diversity

Full descriptions of morphological mutants and the genes that control them were published in the "Barley Genetics Newsletter" in 1997 (http://wheat.pw.usda.gov).

Two-Row versus Six-Row Barley

Barley has a single floret in each spikelet. There are three spikelets at each rachis node, alternating on opposite sides of the barley head or spike. In two-row barley, the central floret is fertile and the two lateral florets are sterile, resulting in a single seed at each node, giving the head a flat appearance (Figure 1a). In the six-row barley, all of the florets are fertile (Figure 1b). The central seeds are round and plump, but the laterals tend to be slightly asymmetric. A single head of barley can produce up to 80 seeds.

The development of lateral spikelets and lateral awns is controlled by alleles at the *vrs1* locus on the long arm of chromosome 2 (2H). Most six-row cultivars possess the recessive *vrs1.a* allele. *Vrs1.b* occurs in many two-row cultivars and is dominant to *vrs1.a*. Rather complex interactions occur with other alleles at this locus, and with alleles at the *int-c* locus on chromosome 4 (4H) to create intermediate phenotypes. Commercial two-row varieties are usually recessive for *int-c* while six-row cultivars have the dominant *int-c* allele.

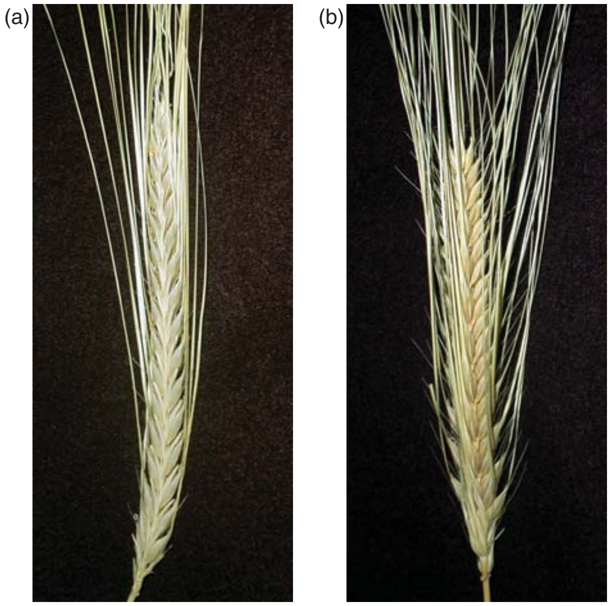

Figure 1 Heads of the: (a) two-row barley and (b) six-row barley.

Two-row varieties usually have a higher number of tillers per plant and plumper, heavier kernels than six-row varieties. Six-row varieties, on the other hand, usually have more seeds per inflorescence. Thus, the compensatory effects of yield components lead to similar levels of yield potential. Two-row barleys are favored for malting throughout most of the world, but in the USA and Mexico, six-row barleys are used extensively for this purpose. Given that two-row and six-row germplasm have historically been maintained in separate breeding pools, one might expect that crosses between the two groups would produce some useful segregants with superior agronomic and malting characteristics. The experience of plant breeders, however, has been that two-row × six-row crosses do not generally provide useful progeny for variety development.

Specialty Types

Most barley varieties are hulled types, with the lemma and palea remaining attached to the seed at maturity. Threshing involves removal of the kernel from the rachis and removal of the awns or hoods from the tip of the lemma. Varieties that are difficult to thresh retain part of the awns or rachis, and may have lower test weight and quality for feed or malting. In hull-less or naked types, the seed separates from the lemma and palea during threshing. The hull-less characteristic is controlled by a simple recessive allele at the *nud* locus on the long arm of chromosome 1 (7H). Hull-less types are produced for various food and beverage uses in East Asia, primarily, China, Japan, and Korea. Hull-less barley is an important subsistence crop in the Andes and Himalayan regions and in Ethiopia. In Canada, hull-less varieties are commonly grown as feed for swine.

Variation in the morphology of barley awns may also influence the suitability of cultivars for particular end uses. Most cultivars have awns, which may be rough or smooth, but awnless types also exist. Hooded types have modified awns that consist of a deformed, inverted floret with leaf-like appendages. This trait is controlled by a single dominant gene at the *Kap* locus located on the short arm of chromosome 4 (4H). Hooded varieties are preferred for hay, silage, and green chop.

Blue aleurone is another common variant of barley, which is controlled by alleles at five *Blx* loci with complementary effects. In general, white aleurone types are preferred because the kernels have a brighter appearance.

Adaptive Characteristics

Different gene pools have evolved in the major barley production areas of the world, with the necessary physiological characteristics for adaptation to each environment. Appropriate maturity, vernalization, and photoperiod response are all major features required for adaptation. The distinct attributes of gene pools may also reflect requirements for important end uses of barley, or personal preferences established over time as the result of the history of barley in the region.

Yield is a primary objective of any breeding program, and steady increases have been attained over the years. Modern cultivars have a higher harvest index than older cultivars, indicating that more of the aboveground biomass has been partitioned to the grain. Improvements in yield are achieved through manipulation of yield components, including number of spikes per unit area, number of kernels per head, and kernel weight. Modern cultivars have several productive tillers per plant and are resistant to shattering. Shattering may be due to seeds separating from the head or from spikes breaking off before harvest. Varieties that are highly resistant to shattering may be difficult to thresh, so breeders must consider several traits simultaneously when making selections.

Good lodging resistance requires short, strong stems and a sturdy root system to anchor the plant in the soil. Lodging has been reduced in modern varieties through increased straw strength and reduced plant height. Semi-dwarf stature may be controlled by one or several genes. Selection for reduced height can have undesirable effects on yield and other characteristics, so again it is important to consider multiple traits when attempting to improve lodging resistance.

Barley varieties should be bred to have the optimum heading date for their target environments. Early maturity is a very important adaptive trait at higher latitudes. For areas with a longer growing season, it is best to grow varieties that take full advantage of the available moisture and favorable temperatures. Barley generally requires long days to initiate flowering, but cultivars vary in their photoperiod sensitivity. Barley has a slightly shorter life cycle than other cereal crops, which may enable it to escape drought in some environments. It is also relatively tolerant to drought, and has the capacity to send up new tillers when conditions become favorable. Plants are most adversely affected by drought during floral initiation and anthesis.

Barley is more salt tolerant than many other crops and is often used to reclaim saline soils. Breeding programs have been successfully carried out for increased salt tolerance. Varieties have also been developed with tolerance to aluminum and soil acidity.

Winter Barley

Winter barley varieties usually require a period of exposure to cool temperatures (vernalization) to initiate flowering, and must also be cold hardy. Facultative varieties do not require vernalization, but they are tolerant to cold temperatures, so they can be planted in the fall or in the spring. Winter barley is potentially higher yielding than spring barley, in areas where it is adapted. However, winter barley varieties are generally not as tolerant to cold as other winter cereals. Cold tolerance in barley has been a difficult trait to improve with conventional breeding methods. It is best to screen breeding material under uniform cold stress in the laboratory, because screening for winterhardiness in the field is seldom reliable. Good lodging resistance and disease resistance are also important characteristics for winter varieties.

Disease and Insect Resistance

Commercial varieties must possess adequate levels of resistance to the disease and insect pests prevalent in their target production zones. It is often stated that qualitative resistance determined by single genes can be overcome by new strains of a pathogen, whereas quantitative resistance, although not absolute, tends to be more durable over time. This is a useful guiding principle for development of resistant varieties, but there are exceptions to this rule. Barley is affected by many diseases, most of which are typical of small grain cereals, e.g., rusts (*Puccinia* spp.), smuts (*Ustilago* spp.), root rots (*Rhizoctonia, Pythium, Fusarium*), bacterial blights, and viruses (*see* **Cereals**: Grain Diseases).

Breeding for insect resistance is a difficult task, because it is usually necessary to rear the insects to obtain uniform, reliable screening environments. Green bug (*Toxoptera graminum*), Russian wheat aphid (*Diuraphis noxia*), jointworm (*Tetramesa hordei*), and the cereal leaf beetle (*Oulema melanopus*) have all received some attention in barley breeding programs.

Breeding Strategies

Breeding Objectives

Breeding programs have traditionally emphasized yield and adaptation. The primary goal has been to

develop malting types, because they receive a premium price in the market.

Furthermore, malting and brewing industries have provided much-needed support for breeding programs. In contrast, relatively little effort has been made to improve barley for feed or food uses.

A common strategy in breeding programs is to breed for good malting quality, with the expectation that resulting varieties will also be good for feed. This approach is based on the assumption that the nutritional requirements of yeast in the brewing process are not too different from those of animals, particularly monogastrics. This theory has been researched and debated for many years. Among existing varieties, there does appear to be some association between quality for feed and quality for malting and brewing. Others argue that existing varieties may not truly represent the potential for high-quality feed barleys, because feed quality has not been a specific objective of breeding programs.

There has been considerable debate about the best ideotype to select to increase yield in barley, because there are often compensatory effects among yield components. Studies of yield components have led to a better understanding of changes brought about by selection, but have provided few useful tools with which to improve selection efficiency.

Quantitative and Qualitative Traits

Many of the important traits determining yield, malting, and feed quality are quantitatively inherited, which means that they are controlled by many genes and are measured on a continuous scale. Quantitative traits may be influenced considerably by environmental conditions during the growing season. Genotype–environment interaction is also common for quantitative traits, which complicates selection in a breeding program, because genotypes that perform the best in one environment may not perform as well in another. Genotypes must be evaluated over multiple sites, and advanced lines must be tested in several seasons to assess quantitative characters.

Qualitative traits that are controlled by one or just a few genes are fairly easy to manipulate in a breeding program, because progeny from crosses between selected parents usually exhibit predictable Mendelian segregation patterns. The situation with quantitative traits is far more complex, because one is never sure whether the parents selected have all of the favorable genes controlling the trait. Furthermore, it is necessary to screen large numbers of progeny to have a good chance of obtaining the favorable genes from both parents in one of the offsprings.

Breeding for Quantitative Characters

Barley breeders and geneticists have approached the challenge of understanding the inheritance of quantitative traits using biometrical tools. Certain traits such as plant height, disease resistance, vernalization requirement, and kernel composition tend to have high heritabilities, which means that the phenotype is determined to a large extent by genetics. Traits with high heritabilities are fairly responsive to selection. Others, such as yield and many malting quality parameters, have lower heritabilities and are more subject to environmental influences. Information about genetic variances and heritabilities have helped to refine selection methods, but still leave many questions unanswered regarding the relationship between genes and adaptation.

The advent of molecular markers and quantitative trait locus (QTL) analysis in the late 1980s provided a means to determine how many genes are controlling a trait, their relative importance in determining the phenotype, and their location on the chromosomes. QTL markers have made it possible to track the transmission of favorable genes from one generation to the next, assisting breeders to choose the best parents for a cross and to select the best offspring.

Barley Cultivation in a Breeding Program

The management practices needed to grow barley in a breeding program are similar to those used in commercial production (*see* **Barley**: Agronomy). Cool temperatures are needed during early growth and establishment and spike development, particularly if crosses are to be made. Anderson and Reinbergs reviewed the techniques available for emasculating and pollinating barley. The anthers must be removed or destroyed when they are still plump and green or greenish-yellow, to prevent self-pollination. Stigmas of the female flowers become feathery and receptive to pollen 1–3 days later. Barley pollinations are most successful in the morning, when the anthers naturally dehisce.

Breeding Methods

The most common approach utilized for barley improvement has been pure line variety development through conventional pedigree and backcross breeding techniques. In other programs, bulks of segregating families are evaluated in parallel with pure line development, to permit assessment of quantitative characters in earlier generations. Single seed descent (SSD) has also been used effectively for spring or facultative germplasm, to rapidly advance material from the F_2 generation to the F_4 or F_5 generation in the greenhouse, where it is possible to grow three

generations in a year. For germplasm with a winter growth habit, one can rely on the natural cold temperature exposure in the field, or use a growth chamber to advance generations more quickly in the greenhouse. Another possibility is to use doubled haploid techniques to advance directly from the F_1 generation to homozygous pure lines. One possible advantage of SSD compared to doubled haploid production is that the additional generations of selfing provide additional opportunities for genetic recombination. Another consideration is the genetic stability of completely homozygous lines derived from haploid methods. With a few exceptions, the general conclusion from experiments comparing conventional, SSD, and haploid breeding methods is that the mean and variance of yield performance are similar for lines derived from the three methods. The choice of methods will depend on breeding objectives, the relative time and expense involved, and the facilities available.

Once the desired level of homozygosity has been attained, single head rows may be evaluated in a breeding nursery for highly heritable traits such as disease resistance and agronomic type. A bulk from a single head row can be evaluated in preliminary yield trials at two locations. In the next generation, adequate seed should be available to initiate advanced yield trials and tests for malting quality.

Mutation Breeding

Chemical mutagens and ionizing radiation have been used extensively to induce new variation in barley. Most mutations are recessive and most are deleterious. Nonetheless, mutation-induced variation has been used in conjunction with conventional breeding methods to generate barley varieties with semidwarf stature, early maturity, and disease resistance. A number of useful mutations in kernel composition have been induced, including high protein, high lysine, low β-glucan, and proanthocyanidin-free mutants.

Doubled Haploids

In barley, several techniques have been used to create doubled haploids from female or male gametes; among the most effective are anther or microspore culture and the "bulbosum" method. To apply the "bulbosum" technique, female F_1 lines of *H. vulgare* are crossed to male lines of *H. bulbosum*. After fertilization, the *H. bulbosum* chromosomes are spontaneously eliminated from the hybrid embryos. The haploid embryos are excised and grown in tissue culture in the presence of colchicine to double the chromosome number. The resulting plants are comparable to those that would be obtained after many generations of selfing from an F_1 plant.

Barley Hybrids

Many sources of genetic male sterility have been identified in barley, and cytoplasmic male sterility and restorer systems are known in *H. vulgare* subsp. *spontaneum*. Gametocide treatments can also be used to induce male sterility.

Although hybrid vigor may be advantageous for hybrid production, it may have undesirable consequences for malting quality. Uniform germination is essential for the malting process, but the F_2 grain harvested from an F_1 hybrid may be highly variable. The use of parents with similar malting quality may reduce this problem, but may also reduce the heterosis in the cross if the parents are genetically related.

Another barrier for hybrid production is the fact that barley normally sheds pollen while it is still in the boot stage, which limits the extent of cross-pollination to a male-sterile female line. Increased cross-pollination and hybrid seed set can be achieved through selection, however.

The Barley Genome

The haploid barley genome size is $(4.9-5.3) \times 10^9$ bp, which is considerably larger than the rice genome. However, only $\sim$12% of the DNA codes for functional genes, and at least 75% of the genome consists of highly repetitive DNA sequences. The genome is organized into regions that have many genes and regions that contain few functional genes.

Barley chromosomes were originally numbered from 1–7 based on relative length during mitotic metaphase. The first five chromosomes have no satellites, and are ordered from longest (chromosome 1) to the shortest (chromosome 5). Chromosome 6 is longer than chromosome 7, and both have satellites (terminal sections of the chromosomes separated by a narrow constriction). Each of the chromosomes of barley can be distinguished with the use of Giemsa C- and N-stains which reveal distinct banding patterns during mitotic metaphase.

Molecular Mapping in Barley

Comparisons of genetic maps among the members of the grass family have shown that different species have many of the same genes and genetic markers, which often occur in a similar order along the chromosomes. Within the tribe Triticeae, the barley genome is highly collinear with the A, B, and D genomes

of wheat, with only a few minor inversions and translocations between the two species. Chromosomes 1–7 in barley are expected to be homeologous to chromosomes 7H, 2H, 3H, 4H, 1H, 6H, and 5H, respectively, in wheat. Some regions of the barley genome are highly collinear with rice, but there are others that show some rearrangements. Nonetheless, genetic probes for rice have proven to be very useful for mapping in barley.

Molecular mapping in barley was facilitated by the existence of many morphological mutants that could be readily scored and assigned to linkage groups. Cytogenetic stocks, such as the barley–wheat substitution lines, were invaluable tools that enabled researchers to assign markers and linkage groups to specific arms of the barley chromosomes, and to determine the location of centromeres. Based on the location of telomeric markers, the combined length of all of the barley chromosomes has been estimated to be ~1500 cM.

Initial genetic maps of barley relied on morphological markers, isozymes, and known genes for disease resistance and storage proteins. Since the late 1980s, many genetic maps of barley have been published using various types of genetic markers including RFLPs, RAPDs, SSRs, and AFLPs. Mapping populations consist of randomly derived, segregating progeny from crosses between diverse parents. The distance between markers in a linkage group is estimated based on the frequency of recombinant (nonparental) genotypes in the mapping population. A database of barley maps is maintained on the GrainGenes website (http://wheat.pw.usda.gov/index.shtml). Collectively, over 2000 molecular markers have been mapped in the barley genome. However, many markers are unique to particular mapping populations, or map to slightly different locations in different genetic backgrounds. A bin map has been developed which attempts to integrate information from many different sources (http://barleygenomics.wsu.edu/). Markers are assigned to ~10 cM segments or bins along each chromosome, which can be identified by specific markers that are common to many of the published genetic maps. This map is a good starting point for researchers who wish to obtain a fine resolution map of a particular chromosome region.

Although the occurrence of genetic markers and their locations on chromosomes are unique to each mapping population, in general, there have been few, if any large-scale rearrangements of chromosomes observed among the mapping populations studied.

The doubled haploid technique has proven to be very useful in developing mapping populations that can be maintained over time. The genetic maps can be refined using increasing numbers of markers, and the lines can be evaluated phenotypically in different experiments for many traits of interest (*see* **Genome Mapping**).

Physical Maps Maps of physical distances along the chromosomes present quite a different picture of the barley genome than genetic maps based on recombination frequencies. Recombination is uncommon in the region of the centromeres, so genetic distances tend to be relatively longer than the physical map in those regions. Recombination appears to be greatest near the end of chromosome arms, but defined regions of high recombination are also found in interstitial areas of each arm. The barley genome is organized into gene-rich and gene-poor regions. There is evidence that the gene-rich areas correspond to areas of high recombination, where marker densities are greatest.

Analysis of QTLs

Individuals in a mapping population are evaluated both for their marker genotypes and for phenotypic traits of interest. Statistical techniques are used to determine if there is a relationship between particular phenotypes and the occurrence of specific marker alleles. If the relationship is significant, then it is assumed that a QTL for the trait is closely linked to that marker. Hayes *et al.* provide summaries of all of the published results from QTL studies in barley (http://barleyworld.org/NABGMP/qtlsum.htm), including traits associated with abiotic stress resistance, agronomic traits, biotic stress resistance, and malting quality. More than 750 QTLs have been identified, and for each category, QTLs have been distributed across all seven chromosomes. A high number of QTLs mapped to the vicinity of the *vrs1* locus on chromosome 2 (2H), which controls the two-row versus the six-row character. It is not known whether this is due to close linkage of QTLs with *vrs1* or due to pleiotropic effects at that locus.

Marker-Assisted Selection

Molecular markers have been utilized successfully to select for closely linked genes and QTLs. Laboratory screening can be carried out during the off-season, to attain more rapid progress in a breeding program. Commonly used markers such as SSRs can discriminate homozygous dominant from heterozygous genotypes, which would have identical phenotypes in a conventional selection program. Marker-assisted selection (MAS) is particularly useful for introducing genes from exotic germplasm, because selection can be carried out both for the genes of interest from the donor parent and the background genotype of the

recurrent parent, reducing the deleterious effects of linkage drag. In the USA and Canada, MAS is being used to incorporate mutations for low phytic acid into elite germplasm. MAS has been used successfully in barley to pyramid multiple genes for stripe rust resistance, providing a higher and more durable level of resistance against diverse strains of the pathogen. MAS was used to develop the variety "Valier" in the USA with superior agronomic and feed quality characteristics. Despite these benefits and successes, MAS has not been applied widely in breeding programs. Its greatest advantage appears to be for traits such as yield and malting quality that have low heritabilities and require extensive screening using conventional approaches. Thomas provides further discussion of the potential and limitations of MAS in barley.

Feed Barley

Barley is fed to livestock both as grain and as forage (*see* **Animal Feed**). Research has shown that there is considerable genetic diversity among barley varieties in terms of nutritional quality and suitability for feed and food uses, but these objectives have not received much emphasis in breeding programs. The price of feed barley is usually determined by simple physical characteristics such as percentage of plump kernels and high test or volume weight. The genetics of feed quality attributes have been reviewed recently.

High test weight is a positive attribute for feed barley, as higher kernel density tends to indicate higher nutritive value, due to higher content of starch and protein, lower fiber, and reduced air space. Kernel plumpness and uniformity are desirable, because plump kernels tend to have higher starch (energy) content. Uniformity is important during feed processing, which may involve dry or steam rolling. Particle size of cracked barley is a characteristic that has recently been shown to influence feed quality for ruminants. Studies to date indicate that larger particle size may confer a slight benefit to animals, but some compromise in particle size may be necessary to optimize all of the parameters used to determine feed quality.

Starch content varies considerably among barley varieties, but typically constitutes ~55% of the kernel. Thus, the main value of feed barley is as an energy source. Typically, starch in barley is composed of 75% amylopectin (a branched chain molecule) and 25% amylose (an unbranched, straight-chain molecule). Genetic variants range from little or no amylose (waxy types) to a high of ~45% amylose. Both mutations are controlled by single genes and tend to be associated with reduced starch and increased β-glucan levels. Waxy types are homozygous recessive at the *wax* locus on the short arm of chromosome 1 (7H). High amylose mutants have recessive alleles at the *amo1* locus on chromosome 3 (3H).

Levels of protein and amino acids vary among barley varieties and are also influenced by environmental conditions. QTLs for grain protein content have been identified on all seven chromosomes of barley, with concentrations of QTLs on chromosomes 2 (2H), 4 (4H), and 7 (5H).

Like all cereals, barley is relatively low in lysine. High lysine mutants were first reported in 1970, and have been the subject of much research and breeding effort. Most of the high lysine mutants are determined by single recessive genes, but many have pleiotropic effects on other components of the kernel, such as the composition of starch, lipid, and protein fractions. Shrunken endosperm is another common attribute of high lysine mutants. The nutritional benefits of high lysine barley have been clearly demonstrated in nonruminant diets, but undesirable pleiotropic effects present a challenge to breeding programs. The agronomic characteristics of high lysine varieties have never met commercial standards, despite intensive breeding efforts.

Compared to other cereal crops, lipid levels are relatively low in barley. Approximately 25% of the kernel lipids occur in the embryo, with the remaining 75% in the endosperm. Attempts to screen germplasm collections for high fat barley mutants have had only limited success; the maximum lipid content identified was ~7%. Nonetheless, barley lipids may be important from a human nutrition standpoint because they contain antioxidant tocotrienols, which inhibit cholesterol synthesis.

The hull constitutes 10–15% of the dry weight of the kernel and is the major contributor of crude fiber, which for the most part is nutritionally unavailable to nonruminants and poultry. The fiber content of hull-less barley is lower, comparable to that in maize and wheat. The source of fiber is primarily the structural components of cell walls (nonstarch polysaccharides and lignin). Acid detergent fiber (ADF) measures insoluble fiber (primarily cellulose and lignin) and is a commonly used indicator of fiber content. Values for ADF range from 2% to 12%. Other components of fiber are soluble to some extent, including the β-glucans, which predominate in the starchy endosperm cell walls, and arabinoxylans (pentosans), which are concentrated in the cell walls of the hull and aleurone. QTLs have been identified for β-glucan content and ADF on chromosomes 2 (2H), 4 (4H), and 5 (1H), indicating that the inheritance of these traits is complex.

The testa of barley contains proanthocyanidins, which are polyphenolic or flavonoid compounds similar to those found in sorghum. There is some evidence

that these compounds may form insoluble phenol–protein complexes, which create haze in beer and reduce the digestibility of protein in animal feed. Other studies have shown that the effects on digestion are minimal because the phenolic compounds occur in very low concentration. Numerous mutants that are deficient in proanthocyanidins have been identified. All that have been studied to date show single-gene recessive inheritance. The most useful mutants from a breeding standpoint appear to be those that alter anthocyanin production in the last step of the flavanoid pathway. Other mutations that affect anthocyanin or proanthocyanin production also reduce vigor and yield.

Minerals occur in barley kernels in low concentrations but are important for animal nutrition. Phosphorus, potassium, and calcium occur in greatest quantities with lesser amounts of chlorine, magnesium, sulfur, and sodium. The hull has the highest concentration of minerals, followed by the embryo, with lowest concentrations in the embryo. Phosphorus is an important mineral in animal nutrition, but 80% of the phosphorus in barley is unavailable because it is bound to phytic acid. Phytic acid also binds to other important minerals, including calcium, iron, magnesium, and zinc. Animals cannot digest these phytate compounds, and the minerals that are not absorbed are excreted in feces. Excess phosphorus in animal wastes can lead to contamination of groundwater, creating environmental problems. Recently, low phytic acid mutants of barley with normal phosphorus levels have shown promise as a means for increasing the availability of phosphorus in animal diets while reducing levels of phosphorus in animal waste.

Animal Performance Tests

Animal performance is the ultimate test for feed quality, but measurement of animal response requires large quantities of barley feed, and considerable time and expense. To effectively breed for feed quality, one would need to assess many genotypes. Several approaches have been developed to measure digestibility, using much smaller quantities of feed. The nylon bag method involves introducing feed into an animal's digestive system in a small mesh bag, and then monitoring the disappearance of the feed after the bag is recovered from the rumen or the feces. The rate of disappearance of feed *in vitro* when incubated with an animal's digestive enzymes is another commonly used measure of digestibility. At some point these results must be verified with full-scale animal feeding trials. Rats, chicks, or weanling pigs are also used for digestion or metabolism trials, and provide good indications of feed quality using limited sample sizes. Results from animal feeding trials have shown that feed quality characteristics in barley are heritable, i.e., they can be manipulated in a breeding program because they are determined to some extent by genetics.

Malting Barley

There are no absolute definitions of malting and brewing quality, due to differences in malting and brewing practices and consumer preferences. In the USA, the American Malting Barley Association (http://www.ambainc.org/index.htm) provides breeders with recommended target levels for traits associated with malting and brewing quality.

The Malting and Brewing Process

During malting, barley kernels are germinated under controlled conditions. Good malting varieties will break dormancy rapidly and germinate uniformly. These characteristics are controlled to some extent by endogenous levels of the plant growth regulators – gibberellic acid (GA) and abscisic acid (ABA). During germination, hydrolytic enzymes are synthesized or activated to partially degrade large starch, protein, and nucleic acid molecules into sugars, amino acids, and nucleic acids that can support the growth of yeast and fermentation processes during brewing. The "diastatic power" of a malt indicates its enzymatic potential to convert starch into sugar. After ~4 days, the green malt is kilned to arrest modification. Modification refers to all of the polymer-degrading processes that occur during malting. During the next step (mashing), the malt is treated with hot water to obtain an extract (wort). Varieties with high extract levels are desired for malting. The extract must provide adequate nourishment to the yeast to permit fermentation, and must contain sufficient sugar to attain the desired alcohol level. During brewing, the malt sugar solution is boiled with hops for seasoning. The solution is cooled and yeast is added to begin fermentation. Finally, the yeast ferments the sugars, releasing CO_2 and ethyl alcohol (*see* **Barley**: Malting).

Genetics of Malting Quality

Genetic control of malting quality has recently been reviewed.

The endosperm is composed of large and small starch granules that are packed in a protein matrix. The amount and types of storage protein in barley affect the rate of modification and malting quality. During malting and mashing, the barley starch should be almost completely degraded into sugars that can be utilized by the brewing yeasts, whereas only ~45% of

the barley protein should be solubilized. Too much protein solubilization is expected to result in beers with poor foaming characteristics. When insufficient protein hydrolysis occurs, the remaining proteins may interact with polyphenols to form beer haze precipitates. Grain protein in the range of 11.5–13.5% is desired for malting. The hordeins are the major storage proteins, and these can be divided into three groups: the sulfur-rich B hordeins, the sulfur-poor C hordeins, and the high molecular weight D hordeins. These proteins are encoded by the *Hor2*, *Hor1*, and *Hor3* loci, respectively, all of which are located on chromosome 5 (1H).

Four amylolytic enzymes are thought to participate in converting the starch in malted barley into fermentable sugars: these are α-amylase, β-amylase, α-glucosidase, and limit dextrinase. A fifth carbohydrase, isoamylase, has recently been discovered, but the precise role of this enzyme is not yet known. The α-amylases are particularly important because they have sufficient thermostability to remain active throughout the mashing process. The *Amy1* and *Amy2* loci, on chromosomes 6 (6H), and 1 (7H), respectively, encode two α-amylase isozymes that differ somewhat in their biochemical properties. Alpha-amylase 2 is expected to make the greatest contribution to α-amylase activity in grain. QTLs for important malting quality traits have been detected in the region near the *Amy2* locus on chromosome 1 in several mapping populations (Figure 2).

Two genes, *Bmy1* and *Bmy2*, on chromosomes 4 (4H) and 2 (2H), respectively, encode the β-amylases. Genetic differences in thermostability of β-amylase could potentially be exploited in breeding programs to improve malting quality.

The enzyme α-glucosidase is encoded by the *Ag1* locus on chromosome 1 (7H), and appears to be important in the mobilization of starch during seed germination.

The enzyme β-glucanase plays an important role in degrading β-glucans in endosperm cell walls during malting. High β-glucans cause problems during modification and filtration and lead to excess haze in the beer. A similar problem may result from an excess of arabinoxylans in the mash. Two genes known to encode β-glucanase isozymes are located on chromosomes 5 (1H) and 1 (7H).

The enzyme systems that reduce the barley storage proteins to "soluble protein" for fermentation are very complex. The rate-limiting step for protein degradation is the hydrolysis of the original proteins into soluble protein by endoproteinases, so it is the activities of these enzymes in malt that will usually determine whether a barley genotype is acceptable for malting. The small peptides and amino acids that are released by the exopeptidases comprise the majority of the free amino nitrogen (FAN) fraction. FAN concentration is measured to indicate how well the original protein material can be utilized by yeasts during brewing.

Several other proteins have been identified that may indirectly affect malting quality by inhibiting the activities of some of the enzymes that are involved in degradation of starch, arabinoxylans, and proteins. α-Amylase 2 and limit dextrinase are examples of enzymes rendered less active by inhibitors. It might be possible to improve malting quality by reducing the effects of inhibitors as well as through selection for increased enzyme levels.

Breeding for Malting Quality

There are a few characteristics that breeders can select routinely to improve malting quality, such as kernel plumpness and protein content, but other assays are expensive or require large sample sizes, limiting the number of genotypes that can be evaluated. Tests for malting quality are usually applied at the prerelease stage. Newly released varieties will be designated as either a malting variety, or by default, a feed barley. To be designated as a malting variety, rigorous test criteria established by the malting and brewing industry must be met. A variety must pass through a series of micromalting and malt analysis tests, followed by pilot-scale malting tests, and finally, plant-scale malting and brewing tests including taste tests. The processes of varietal development and quality testing may take 15 years.

Many of the traits determining malting quality can be improved through breeding, but developing a variety that has good agronomic characteristics and falls in the accepted range for all quality traits is a challenge. Figure 2 shows an SSR map of the 88Ab536/Strider population. "88Ab536" is a variety developed by the USDA at the University of Idaho that combines winterhardiness from a Nebraska line "NE76129" with the malting quality of "Morex." "Strider" is a highly productive winter feed barley adapted to the Pacific Northwest of the USA. The graph reveals results from QTL analysis of malting quality in four different populations, showing QTLs consistently in the region of the *Amy2* locus on chromosome 1 (7H), and on the short arms of chromosome 4 (4H) and 7 (5H). Molecular markers can be used to simultaneously select for this quality profile and important QTLs determining cold tolerance. The ability to make selections for malting quality at early stages in the breeding program should greatly increase the likelihood that good malting varieties will reach the prelease stage for pilot-scale malt testing.

Future Directions

Experience with QTL analyses has shown that QTL results may be as variable and subject to environmental influences as the traits they were meant to define. Efforts are underway to develop expressed sequence tag (EST) libraries, which are cloned sequences of cDNA derived from actively transcribed mRNA. This will lead to identification of genes that have a direct functional relationship to quantitative trait expression, which will serve as more precise targets for MAS.

Discrepancies between the genetic and physical maps of barley present problems for fine structure analysis of gene function. QTLs that map to regions corresponding to large physical distances may be suitable for MAS, but are not sufficient for map-based cloning. Several approaches are being used to obtain higher resolution maps. Near isogenic lines are proving to be useful tools for genetic dissection of particular traits and chromosome regions. SNP and STS markers are being used to saturate chromosome regions with low recombination frequencies and low marker densities. Two barley yeast artificial chromosome (YAC) libraries and a barley artificial chromosome (BAC) library have been developed. The BAC library will be a useful tool for physical mapping of the barley chromosomes and map-based cloning.

Despite the potential of MAS to improve quantitative traits, there are only a few examples of the application of this technique in applied breeding programs. One of the reasons for this is the high cost/benefit ratio for application of molecular approaches, compared to conventional breeding methods. The development of microarray chip technology may overcome this barrier by greatly increasing the rate of throughput and information content of laboratory samples.

Another limitation of QTL analysis to date is that it may be specific for the mapping populations that are utilized. Germplasm from important barley production areas of the world, including Africa, Asia, the former USSR, and the Middle East, is under-represented in these studies. New statistical techniques for association mapping may permit rapid identification of potentially useful QTLs in a broader array of germplasm.

The likelihood of obtaining acceptable varieties is greatest when crosses are made between elite varieties. Breeders typically cross elite varieties and attempt to improve specific traits such as disease resistance, while maintaining the desired agronomic and quality characteristics. This approach is inherently conservative because it relies on a limited gene pool. There is a wealth of genetic diversity with potential utility in cultivated barley, and perhaps in *H. vulgare* ssp. *spontaneum* as well. Effective use of these resources requires long-term efforts to develop useful source populations. The availability of better selection techniques for malting quality and yield using molecular markers will greatly facilitate the use of more diverse genetic resources.

Agronomy

R D Horsley and M Hochhalter, North Dakota State University, Fargo, ND, USA

Introduction

Barley is the cereal crop with the widest range of production areas in the world. It is often the last cereal crop grown at the highest altitudes in the Andes and Himalayan mountains; adjacent to the deserts of Africa, the Middle East, and China; and near the Arctic Circle in the northern reaches of Asia, Europe, and North America. Barley has many uses, including livestock feed, human food, and for production of malt. Because of the diverse growing areas for barley and its many uses, production practices vary greatly. Production practices for malting barley are more stringent than those for barley produced for other uses because of the specifications put on the crop by the malting and brewing industries. Barley to be used for malting must meet specifications for germination, kernel size and weight, grain protein, and many other traits. Barley for livestock and human food uses has much fewer restrictions.

Growth Stages

Before the effects of different production practices and environmental stresses on the performance of barley can be understood, knowledge of the different growth stages and yield components of barley are needed. Different scales are available for describing the growth of barley, including the Feekes, Haun, and Zadoks growth stage scales. Figure 1 compares these three different growth stage scales and lists suggested production practices for spring barley grown in the Mid-west United States.

Components that determine yield in barley are the number of spikes per area, the number of kernels per spike, and kernel weight. Stresses during a certain period of the growing season will reduce one or more of the yield components. Factors affecting the number of spikes per area include those that directly affect the number of plants per area and the number of tillers per plant. The number of plants and tillers can be impacted most severely from sowing to shortly before the jointing stage. Factors that can reduce the number of plants per area include sowing rate, insufficient moisture for germination, waterlogged soils following sowing that may kill the seed or cause soil crusting, winter-kill, weed competition, insects, and diseases. The number of tillers per plant can be negatively impacted by excessive temperatures, insufficient moisture, insects, and weed competition.

Before jointing, the developing barley plant is tolerant to freezing temperatures because the growing point is protected below the ground. At the jointing stage, the growing point of the barley plant comes aboveground and is vulnerable to environmental stresses that will cause fewer spikelets per spike. The number of kernels per spike also can be impacted by stresses during pollination, such as freezing or excessive temperatures that can kill the pollen. Pollination in barley generally occurs during the late-boot stage.

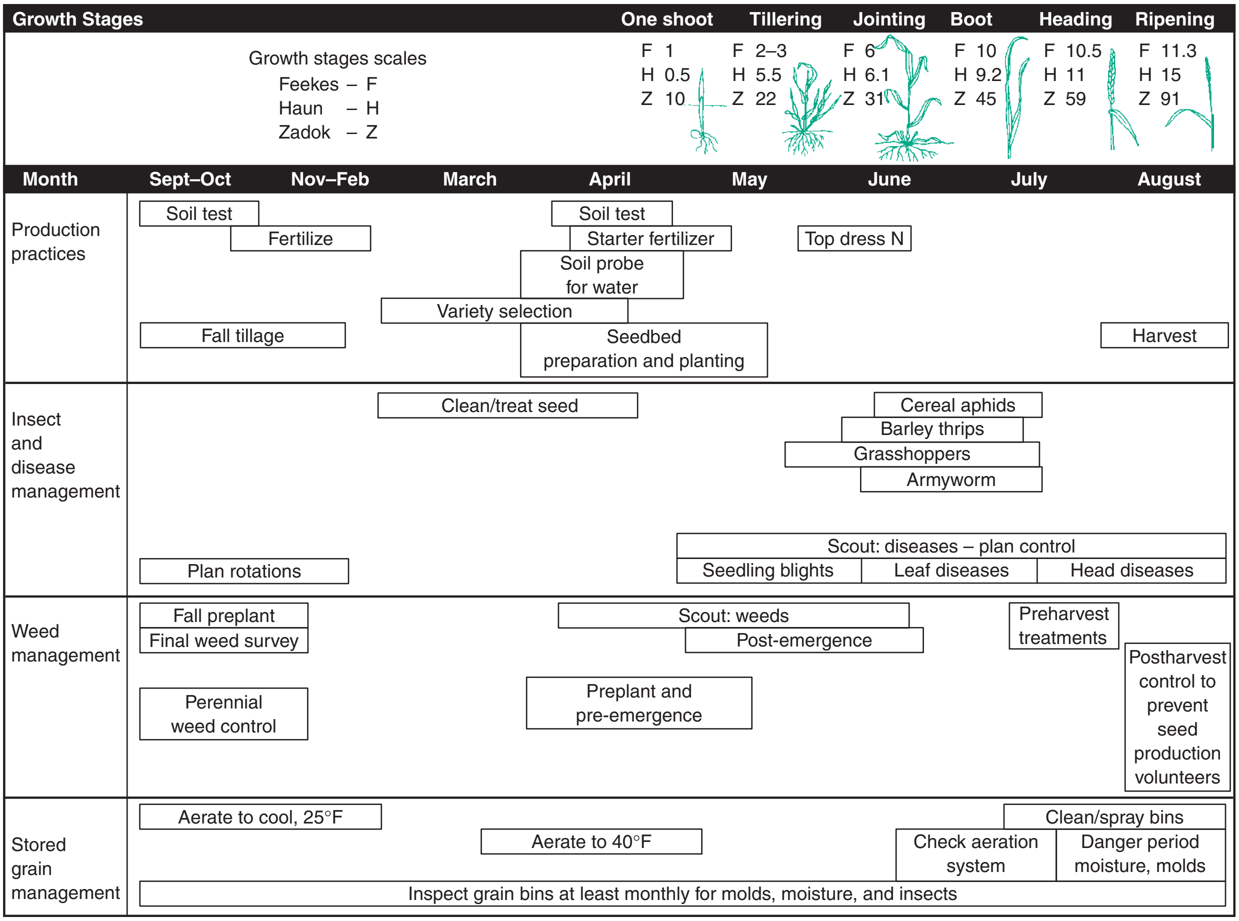

Figure 1 Barley growth stages and suggested production practices for barley produced in the Midwest United States. (Reproduced with permission from Peel MD (2000) *Barley Production Guide*. Fargo, ND: North Dakota State University Extension Service.)

Stresses following fertilization will affect kernel weight and plumpness, possibly reducing grain quality. These stresses include excessive temperatures, insufficient moisture, weed competition, diseases, and insects. Damage to the flag leaf and the leaf below it by insects or diseases more severely impacts kernel weight than damage to the lower leaves. Thus, growers are encouraged to scout their crop to make sure that the top two leaves of the plant are free from damage caused by disease and insects. Thin lightweight kernels are undesirable for malting because they typically are high in grain protein and are difficult to malt uniformly. Also, the resultant malt generally has overall poor-quality malt, especially low malt extract.

Plant Nutrition

Barley responds well to fertilizers containing nutrients limiting in the soil, especially nitrogen. When nitrogen is limiting, additional amounts applied through different forms of fertilizer will increase yield and grain protein. The amount of fertilizer to apply is dependent on the end use of the harvested grain, soil test results, and expected yield. In most areas of the world except North America, barley used for malting must have grain protein below 11.5%. Many North American maltsters and brewers will accept grain protein up to 13.5%. One reason why brewers in this region accept higher barley grain protein levels is that they often use higher levels of brewing adjuncts (e.g., corn or rice) that have a diluting effect on the total barley protein in the beer. There are no upper limits on grain protein content on barley for livestock feed or human food uses.

Nutrients and amounts of them to add are dependent on the results of a soil test that measures residual levels of nutrients. Table 1 is an example of a soil recommendation chart used in the Midwest United States based on soil test results and yield goal. Higher levels of nitrogen fertilizer are recommended for barley produced for nonmalting uses; however, excessive nitrogen can result in a lush crop that is prone to lodging and foliar diseases. Also, excessive fertilizers can be environmentally problematic in well-drained

Table 1 Nutrient recommendations for malt and feed barley in the Mid west United States

Yield goal ($t\ ha^{-1}$)	*Soil N plus fertilizer N required for malt barley ($kg\ ha^{-1}\ (0.6\ m)^{-1}$)*	*Soil N plus fertilizer N required for feed barley ($kg\ ha^{-1}\ (0.6\ m)^{-1}$)*		*Soil test phosphorus (ppm)*					*Soil test potassium (ppm)*

soils or areas with a high water table if they leach into the groundwater.

Accurate estimates of a yield goal are extremely important in choosing the proper amount of nitrogen fertilizer to apply. Application of too much nitrogen fertilizer can result in the barley having excessive protein and being rejected for malting. In environments and/or years where moisture is limiting, the recommended rates of nitrogen to apply to malting barley may be excessive and result in unacceptable barley for malting. As mentioned earlier, high-protein barley is difficult to malt uniformly and results in poor-quality malt. Thus, it is not uncommon for growers to apply less than the recommended rate of nitrogen to increase their likelihood of producing acceptable malting barley.

Fertilizers can be applied throughout the growing season; however, most nitrogen is applied prior to sowing to ensure sufficient amounts are available for seedling establishment and tillering. Growers sowing barley during spring often apply their nitrogen during fall to reduce their spring workload; however, fall application of fertilizers is not recommended for well-drained sandy soils because excessive leeching may occur over winter. The method of nitrogen fertilizer application is dependent on the source of nitrogen. Anhydrous ammonia is knifed into the soil ~10–15 cm below the soil surface. Nitrogen in the form of urea, other dry formulations, or liquid can be broadcast over the soil and then incorporated into the soil using shallow tillage. In soils deficient in phosphorus and potassium, these nutrients are often applied during sowing to supply a "quick" start for the crop. Top dressing of fertilizers during the growing season is an option that is available if a nutrient deficiency is detected.

Knowledge on the effects of micronutrient deficiencies on barley is limited. Under some conditions, barley has been found to respond favorably to addition of chloride, copper, iron, and sulfur. More is known about the toxic effect of some micronutrients. In low pH soils, in areas of South America and Australia, aluminum toxicity can be a problem. Also, in areas of Australia, boron toxicity can severely interfere with plant growth. To overcome problems associated with these problematic soils, barley cultivars have been developed that are tolerant to higher levels of boron and aluminum.

Cultivar Selection

Choice of cultivar for production is especially important for growers producing barley for malting and as a method to combat potential problems such as diseases, insects, and micronutrient toxicity. In all major malting-barley-growing regions, different

organizations evaluate and determine which barley cultivars meet their specifications. To aid barley breeders, the organizations responsible for evaluating potential new malting barley cultivars often provide specifications that cultivars must possess before they will be recommended for malting and brewing (*see* **Barley**: Malting). Some of these groups also provide lists of cultivars that fit their specifications and are recommended for malting and brewing. In choosing malting barley cultivars for production, growers need to be aware of what cultivars are preferred by their local buyer. Even though there may be up to a dozen cultivars recommended for malting in a grower's area, local buyers may be purchasing only one or two specific cultivars. Growers should not only consider yield potential when choosing a malting barley cultivar to produce, but also its grain protein and kernel plumpness when grown in their area. For example, if going into the growing season, the grower knows that stored soil moisture is limiting and residual nitrogen is high, they should choose a cultivar that has inherently lower grain protein even if it has a lower yield potential. Because of the premium paid for malting barley versus feed barley, it is often better to sacrifice some yield to ensure the crop has acceptable grain protein and kernel plumpness.

Recommendations for barley cultivars to be used for livestock feed or human food are limited. "Valier" barley was developed by the Montana Agricultural Experiment Station in the United States specifically for feeding to cattle. However, much of the barley for the livestock market is grain that has been denied for purchase for malting due to one or more deficiencies (e.g., excessive grain protein, diseased kernels, low kernel weight, etc.). Barley cultivars for human food often are bred to have greater levels of soluble fiber, especially beta-glucan, and to have the hull-less character. Cultivars with these characteristics have been found to have hypocholesterolemic effects and a low glycemic index that may be beneficial in regulating blood glucose and reducing the risk of diabetes.

Most barley recommended for malting and brewing has the two-rowed spike type (Figure 2). However, in North America over 50% of the barley used for brewing is six-rowed. Historically, six-rowed barley has had higher enzyme levels that are required in beers brewed with adjuncts. Beers brewed with adjuncts tend to be lighter than traditional European-style beers made with 100% malt.

Figure 2 Comparison of the spike morphology of two-rowed barley (left) and six-rowed barley (right).

Sowing Date, Depth, and Rate

The timing of sowing varies greatly across the globe. Barley with a spring growth-habit is generally sown in spring; however, it can be sown during fall in environments where winters are not severe and more than one cropping season per year is available. For example, spring barley often is sown in fall in east-central China. In this situation, barley is sown in October, harvested in early May, and rice is sown shortly thereafter. Another example of fall-sown spring barley occurs in the southwest United States. In this desert area, barley is sown in October, harvested in April, and a forage crop such as sudan grass is then sown. Areas where spring barley is predominantly spring-sown include Australia, northern Europe and Asia, North America, and South America. Barley with the winter-growth habit is generally less winterhardy than winter wheat; therefore, winter barley is grown in areas with less severe winters. In Germany, the ratio of winter to spring barley is $\sim 60:40\%$.

The desired sowing depth of barley is between 20–30 mm; however, the sowing depth may need to be deeper, as the seed is placed in moist soil. Because of the emergence mechanism of barley, it should not be sown deeper than 55 mm. The type of seedling emergence in barley is referred to as the elongating coleoptile. In this type of emergence, the maximum

length of the coleoptile will be only 35–55 mm. During seedling emergence, the coleoptile ceases to elongate once it breaks through the soil surface and is exposed to sunlight. Emergence of the remaining leaves occurs through the tip of the coleoptile. During germination, the stem internodes do not elongate, so the first node, coleoptilar node, and terminal bud (i.e., growing point) remain at the sowing depth. About 2–3 weeks following emergence for spring-sown barley and after vernalization and temperatures warm up in the spring for winter barley, the second internode of the plant elongates until the terminal bud and other stem nodes are ~10 mm from the soil surface. The first and second nodes remain at the sowing depth, and the tillers and crown roots develop from the remaining nodes.

The seeding rate for barley is dependent on many items, including the type of barley being grown (two-rowed versus six-rowed) and whether the barley is being grown under dryland or irrigated conditions. The desired plant population can range between 215 and 375 plants m^{-2} (i.e., between 2.15 and 3.75 million plants ha^{-1}). The lower plant population is recommended for barley grown under dry conditions while the higher population is recommended for barley grown under irrigation. Also, since two-rowed barley generally produces more tillers than six-rowed barley, lower plant populations for two-rowed barley can be used.

To determine the correct number of seeds to sow per hectare, the grower must know the desired final plant population, the estimated seedling mortality, and the percent germination of the seed. The estimated seedling mortality can be based on prior experience and the percent germination of the seed is usually supplied with the purchased seed. If the seed is old or if the germination is not known, the grower needs to determine the percent germination themselves. This can be done using a simple test where 100 seeds are placed between two pieces of damp paper towel and counting the percent germinated seeds after three days. It is important that the paper towel is kept moist during the 3-day period. The number of seeds to sow per hectare can be calculated using the following formula:

$$\begin{aligned}\#\text{ of seeds to sow ha}^{-1} = {} & \#\text{ of desired plants ha}^{-1} \\ & \times (1/(1-\%\text{ seedling mortality})) \\ & \times (1/\%\text{ germination})\end{aligned}$$

For example, if the grower desires a population of 3.0 million plants ha^{-1}, the seedling mortality is 3%, and the percent germination is 95%, the grower would need to sow ~3.25 million seeds ha^{-1} (i.e., (3.0 million plants ha^{-1}) × (1/0.97) × (1/0.95)).

The seeding rate to achieve the desired plant population is dependent on seed weight. To determine the correct seeding rate the grower can use the following formula:

$$\begin{aligned}\text{kg of seed ha}^{-1} = {} & \#\text{ of desired seeds ha}^{-1} \\ & \times (1000\text{-kernel weight}/1000)/1000\end{aligned}$$

For example, if the grower wants to sow 3.25 million seeds ha^{-1} and the 1000-kernel weight is 42 g, the grower would need to sow 136.5 kg ha^{-1} (i.e., 3.25 million seeds × (42/1000)/1000).

Irrigation

Barley has a high water-use efficiency and can extract moisture from a 0.8–1.0 m depth. Moisture needs throughout the growing season is ~400 mm. Because of its high water-use efficiency, barley is most often grown without irrigation. However if irrigation is used, it is done more for malting barley than feed barley because of its higher potential value and the requirement for plump kernels and low grain protein.

The goal of any irrigation schedule is to maintain available soil moisture levels above 50%. Management of any irrigation schedule is important because insufficient water will result in reduced yields, thin kernels, and excessive grain protein for malting. Excessive moisture will result in grain that lodges, making it prone to disease and difficult to harvest. Also, lodged grain often has thin kernels and high grain protein that may make it unsuitable for malting.

Disease Control

The list of barley diseases caused by bacteria, fungi, and viruses is extensive. Table 2 provides a partial list of important bacterial, fungal, and viral diseases of barley. Barley diseases exist that can infect all parts of the plants. A series of different root rots severely limit root development. The effects of this group of diseases are especially noticed during dry years or in dry areas of the field such as hilltops because roots are unable to uptake sufficient water. Diseases that affect the foliage of the plants such as the rusts, blotches, and leaf blights can severely reduce the photosynthetic capacity of the plants. These diseases often result in yield losses and excessive grain protein for malting due to reduced kernel weight. Finally, diseases of the spike such as the different kernel blights and smuts can reduce yield, but more importantly can limit the marketability of the grain. Grain that is contaminated with smut or kernel blight can be severely discounted or rejected at the point of sale. Also, some pathogens such as the kernel blighting *Fusarium* spp. produce

Table 2 A partial list of common diseases of barley, causal organism, and most common growth stage of infection

Disease	*Causal organism or vector*[a]	*Plant parts infected*
Bacterial		
Bacterial leaf blight	*Pseudomonas syringae*	Leaves
Bacterial kernel blight	*P. syringae*	Kernels
Bacterial blight	*Xanthomonas translucens*	Leaves
Fungal		
Common root rot	*Bipolaris sorokiniana*	Roots
Pythium root rot	*Pythium* ssp.	Roots
Rhizoctonia root rot	*Rhizoctonia solani*	Roots
Spot blotch	*B. sorokiniana*	Leaves
Net blotch	*Pyrenophora teres*	Leaves
Scald	*Rynchosporium secalis*	Leaves
Powdery mildew	*Erysiphe graminis*	All aerial plant parts
Leaf rust	*Puccinia hordei*	Leaves
Stripe rust	*P. striiformis* f. sp. *hordei*	Leaves
Stem rust	*P. graminis* f. sp. *tritici*	Leaves
Covered smut	*Ustilago hordei*	Kernels
Loose smut	*U. nuda*	Kernels
Head blight (scab)	*Fusarium* ssp.	Kernels
Viral		
Barley stripe mosaic	Seed-borne	Leaves
Barley yellow dwarf	Aphids	Leaves
Barley yellow mosaic	Soil-borne fungus *Polymyxa graminis*	Leaves

[a] Causal organism for bacteria and fungi, and vector for viruses.

mycotoxins. In the Midwest United States in 2000, barley with greater than 0.5 ppm of the mycotoxin deoxynivalenol (DON) was discounted nearly $20 per ton. Grain with DON greater than 3.0 ppm was rejected entirely for malting.

Disease control can be accomplished by use of resistant cultivars, cultural methods, and chemicals. The easiest and most cost-effective method of disease control is growing resistant cultivars. Cultivars that are resistant or tolerant to most economically important diseases exist; however, like all cultivars they have limited areas of adaptation. When a disease is new to an area or resistance breaks down in currently grown cultivars, it may take breeders a short time to develop improved cultivars if they have been working on the problem. However, when a disease is new to an area and no resistance is found in any of the adapted cultivars or advanced breeding germplasm, it may take more than 10 years to develop new resistant cultivars. Development of disease-resistant malting barley cultivars may take even longer, since the breeder must incorporate disease resistance with the stringent characteristics specified by the malting and brewing industry.

Crop rotation and tillage are cultural methods that are commonly used for disease control. Many of the diseases that infect barley also infect other crops. For example, *F. graminearum* and *Bipolaris sorokiniana* are the causal organisms of common root rot in barley and wheat, and *F. graminearum* is the causal organism of head blight in barley and wheat, and stalk rot in maize. Thus, when choosing a crop rotation, growers must be aware of their potential disease problems and alternative host crops of those diseases. A minimum of 1 year between susceptible crops is needed; however, to ensure reduction of potential disease problems, 2–3 years between susceptible crops is preferred.

Tillage can reduce potential disease problems by burying crop residue that harbors pathogens. However, as more growers use minimum tillage or no-till methods, the potential for residue-borne disease is likely to increase. Chemical control for disease management can include application of fungicides applied to seed and foliage, and insecticides to control virus vectors. Laws controlling chemicals that can be applied to crops differ for each country; thus, the mention of a particular chemical does not indicate that it is a permissible treatment everywhere. Fungicides applied to seeds are done to protect the seedlings from root rot, control loose smut (incited by *Ustilago nuda*), covered smut (incited by *U. hordei*), and other seed-borne diseases. Chemicals often used for seed treatment include carboxin; carboxin with captan, maneb, or thiram; imazalil; metalaxyl; and tebuconazole.

Application of fungicides for foliar-disease protection is generally done to protect the top two leaves of the plant. However, control of polycyclic diseases

such as leaf rust (incited by *Puccinia hordei*) and stripe rust (incited by *P. striiformis* Westend f. sp. *hordei*) may require fungicide applications to seedlings and additional applications later in the season to protect the plants' top two leaves. Adequate coverage of the spikes by fungicides to control the kernel-blighting diseases is difficult because the lemma awns intercept the chemical before it reaches the kernel surface and the fact that most crop sprayers are designed to apply chemicals to weed and crop foliage. A sprayer configuration comprised of front and back-facing nozzles has been found to provide the best coverage of spikes with fungicide.

Insect and Nematode Control

Damage due to insects can be grouped into two categories: (1) damage due to consumption of plant parts during feeding and (2) damage due to virus or toxins transferred during feeding. Insects that can cause substantial losses due to plant consumption include grasshoppers, crickets, thrips, the cereal leaf beetle, wireworms, and cutworms. Wireworms tend to cause their damage by feeding on the roots and underground portions of the plant while the remainder of insects listed above cause their damage by feeding on the aboveground portions. Control of these insects is recommended after their population is above an economic threshold. Wireworms and cutworms need to be controlled early during the growing season so the plant population is not significantly reduced. Similar to controlling diseases, growers need to ensure that the top two leaves of the plant are not damaged by grasshopper, crickets, and other foliage-eating insects since they are the most important leaves in contributing photosynthates to the developing kernels.

Four aphids are known to transfer the barley yellow dwarf virus during feeding. These aphids are: the bird cherry-oat aphid (*Rhopalosiphum padi*), corn leaf aphid (*R. maidis*), English grain aphid (*Sitobion avenae*), and green bug (*Schizaphis graminum*). Barley yellow dwarf is the most important viral disease of barley and is found worldwide. Use of resistant cultivars is the best control for this disease. However, if resistant cultivars are not available, systemic insecticides can be used to control aphids if their population gets above the economic threshold.

Hessian fly (*Mayetiala destructor*) is a pest of wheat throughout the world and can cause damage to barley as well by injecting a toxin during feeding. However, damage to barley is rare and this insect is not often considered a serious pest of barley.

Two nematodes are known to cause economic damage to barley. Cereal cyst nematodes are a complex of several species of nematode that belong to the genus *Heterodera*. In seriously damaged plants, the roots are stunted and produce many lateral roots. Early aboveground symptoms of the plants infected by cereal cyst nematode mimic those caused by nutrient deficiencies. When older infected plants are pulled from the ground and the roots are examined, the white cysts attached to the roots can be identified. To confirm that damage is due to cereal cysts nematodes, a laboratory diagnosis is encouraged. Control of this pest has been accomplished using several different methods, including crop rotation, use of resistant cultivars, and use of fungal biocontrol agents.

Cereal root-knot nematode, belonging to the genus *Meloidogyne*, is the other nematode that can cause economic yield losses in barley. Damage caused by this complex of nematodes is similar to that of the cereal cyst nematodes. The root system of infected plants appears bushy due to a stunted root system with many lateral roots. When adult plants are pulled from the ground and the roots are examined, galls ranging from small to near pea-sized can be seen. To confirm infection by cereal root-knot nematodes, a laboratory diagnosis is recommended. Control of damage due to cereal root-knot nematodes is usually accomplished using crop rotation.

Weed Control

Weed control is an integral part of almost every commercial barley production scheme. Excessive weeds can reduce yield and negatively impact grain quality for malting by reducing kernel plumpness and increasing grain protein. Many growers use tillage, herbicides, crop rotation, or a combination of these practices to control weeds in their fields. In some areas of the world, these methods may not be feasible or available because of environmental or marketing circumstances.

Tillage is a viable option for most barley production systems including organic production, where herbicide use is not an option. Most weeds are easily controlled with tillage when they are small and can be covered by small amounts of soil. Barley can be harrowed or rotary-hoed either pre-emergence (when coleoptile is 10–15 mm below the ground) or post-emergence (2–3 leaf stage). At these stages, the crop can more easily overcome damage and root pruning caused by tillage implements. Since tillage is a nonselective weed-control method and both crop and weed species can be injured, care must be taken when harrowing, rotary-hoeing, or using other types of tillage. Many times, the barley stand can be reduced 20% or more by using tillage. In addition, the level of weed controlled may not be an

acceptable excuse for subjecting the barley crop to this harsh, nonselective method of control.

Herbicides are the most popular method of weed control for growers worldwide. In a properly managed integrated pest management (IPM) program, herbicides can be a valuable asset. Herbicides can provide both nonselective and selective means of controlling weeds in a cropping situation. For most broadleaf weeds, many herbicide options are available. These broadleaf herbicides take advantage of obvious physiological differences between grass and broadleaf plants. Grass weeds can be the most important yield-limiting factor in a crop production situation. Since barley is in the same taxonomic family as other grasses, Poaceae, grass weed control in barley is difficult or impossible to achieve without some injury.

Since there are fewer chemical options when controlling grass weeds, resistance to specific herbicides and herbicide families is becoming a major problem. For this reason, it is important to use different herbicide families when controlling weeds to remove resistant biotypes of various weed species. Many weeds have developed resistance to acetolactate synthase (ALS) and acetyl CoA carboxylase (ACC-ase) inhibiting herbicides. Kochia (*Kochia scoparia*) is an example of an ALS inhibitor-resistant weed that has become a major problem. Resistant kochia plants evolved when herbicides such as chlorsulfuron and metsulfuron-methyl from the ALS inhibitor group of herbicides became popular in crop protection. Kochia plants developing resistance to one of these herbicides also become more tolerant of herbicides that affect the same exact site of enzymatic activity. As a result, kochia may be resistant to other herbicides that belong to the same group. Only one plant is needed to create a resistant population that can exponentially increase over time. More serious weed-control problems can occur when weed species develop resistance to more than one herbicide family or group; this is known as multiple resistance.

Crop rotation plays an important role in weed control. By growing a different crop on the same piece of land each growing season, different herbicides can be used; thus, reducing the chance of resistant weed biotypes becoming problematic. By growing a broadleaf crop before rotating into barley, the grower typically has a better opportunity to get some grass weeds under control. Likewise, volunteer barley from the previous crop can be easily controlled in a broadleaf crop by a number of different herbicides the following growing season. Another good crop rotation practice is rotating spring and winter crops. This allows herbicide applications at different times during the year and may control certain weed populations that may not be controlled during a spring-type cropping scenario.

Not all weed control options are available to every barley grower. Environmental conditions, such as lack of moisture, may cause tillage to be a prohibitive practice. For example, tillage may not be an option in a no-till situation, but may work in a minimum-till setting. Organic growers are restricted from using herbicides on weeds and genetically modified crops in their rotations, but may get weeds under control by tillage and use of crops like rye in their cropping rotation. By using any of these methods of weed control, growers can protect their yield potential and make their crop more profitable.

Harvesting, Storage, and Transport

R J Henry, Southern Cross University, Lismore, NSW, Australia

Introduction

Harvesting, storage, and transport of barley aims to deliver a year round supply of sound grain to a variety of barley end users. The barley must satisfy the demands of the food, feed, and malting industries. In turn, the malting industry must deliver a product suitable for food, distilling, and brewing industries. Barley for malting must retain good germination, and this is a key issue in the handling of barley. Harvesting aims to recover maximal yield of barley and avoid environmental damage and contamination. Storage must maintain varietal purity and avoid loss of germinability. Transport should preserve storage conditions and ensure that the grain is not contaminated.

Unique Features of Barley

The harvesting, storage, and transport of barley require consideration of the issues associated with other grains and the additional constraints imposed by the use of barley in malting. Malting requires clean grain that can be germinated uniformly. Barley is also unique in comparison to grains such as wheat in being a hulled grain (except in the case of naked barley). The lemna and palea make up a husk that adheres to the grain. The presence of the husk provides some protection to the grain against abrasion during handling. The husk is, however, a site for microbial infestations (fungal and bacterial) that may be more difficult to remove than those on the surface of naked grains. Hull-less barley varieties may have very different storage and handling properties.

Harvesting

The timing of harvest aims to optimize yield and quality while minimizing environmental risks such as preharvest sprouting, associated with delayed harvesting. The grain must be mature before it is harvested. Early harvesting will result in higher moisture content of the grain, which will require careful storage and/or drying. The timing of harvesting may be more critical in some environments than others, so harvesting capacity must be sufficient to harvest the crop within a very short period of time in high-risk environments. Areas with a high rainfall, conducive to preharvest sprouting, require this approach. In some areas, high humidity can restrict the time available for harvest each day. Storage and transport capacity requirements may also be determined by these factors. Crops can be harvested at very high moisture contents (more than 50%) with combines but yield will be lost, because the crop would not have reached maximum grain dry-weight and costly grain drying would be needed before storage. The grain must be mature before it is harvested.

Grain Cleaning

"Dockage" is a term used to describe the grading of grain such as barley, by removing nongrain parts of the plant and other debris.

Grain Size

The size of barley is a key measure of grain quality, and harvested grain is also subjected to screening to remove small and broken grains prior to storage or transport. The proportion of grain in 2.5 and 2.8 mm sieves is a further measure of grain plumpness used to assess barley quality. The uniformity of size is important because of the influence of grain size on the rate of modification of the grain during malting. Grain may be fractionated to manipulate the uniformity before use in malting.

Skinning

The skinning of barley during harvest or handling can result in loss of germination potential. Skinning may result in the loss of the embryo or damage to tissues such as the aleurone, important in malting. However, some abrasion of the grain may assist malting by accelerating water absorption during steeping or by contributing to the breaking of dormancy.

Shattering

The shattering of barley results in poor recoveries of grain in the field and therefore significant losses. This is more likely when harvesting dry grain or grain that

has matured under unfavorable environmental conditions.

Grain Drying

The drying of barley requires extra care to preserve germinability for malting. Heat and mechanical damage may result from some drying protocols. Aeration of stored grain with a fan can both reduce the grain temperature and dry the grain especially if dehumidified air is used or low ambient humidity prevails. Heated air needs to be used with caution to avoid damage to the viability of the barley, especially in the case of malting barley.

Storage

Defined hazards associated with storage of grain include:

- excessive moisture;
- extremes of temperature;
- microbal infestations;
- insects and arachnids (e.g., weevils, beetles, and mites);
- rodents (e.g., mice and rats);
- birds (both before harvest and in grain stores);
- biochemical deterioration; and
- mechanical damage in handling.

Other general concerns of particular significance in relation to barley are introduction of environmental contaminants, preservation of germinability, and avoidance of admixture.

Environmental Contaminants

Environmental contaminants in barley are of concern to brewers as these may contaminate the finished beer. These contaminants include soil pollutants and naturally occurring toxins (e.g., heavy metals), components of fertilizers, fungicides and pesticides, and air pollutants. Seeds are often coated with preparations designed to protect the seeds from pests and diseases when planted in the field. The composition of these seed protectants may be of concern to brewers. Fungi introduce anther type of hazard, the possible presence of mycotoxins. Treatments to prevent the growth of fungi in stored barley may be required. Beer consumers are considered very sensitive to concerns about the purity of the product, and brewers are keen to ensure that their product retains a reputation for purity relative to competing products. This issue has resulted in the introduction of detailed quality assurance protocols to control the production and storage of barley. The use of insecticides and fungicides, especially those applied during storage may result in residues on malt that could end up in beer or other cereal products.

Germinability

Storage of malting barley also aims to preserve the viability of the grain. This is only a constraint for seed uses in other grain species. A ready germination of at least 95% of the grain is the usual standard applied to the acceptance of barley for malting. A supply of barley with high viability is required throughout the year to allow malting facilities to be used to maximum capacity. Storage of malting barley for at least 12 months after harvest is required unless transport between northern and southern hemispheres is used to supply the maltings. However, because of transport costs, most malting is based on locally produced barley.

Moisture Content

The relationships between moisture content and temperature and longevity in storage can be used to determine the probable storage life of barley samples. Equations to predict the safe storage period for barley based upon temperature and moisture content have been developed (Figure 1). These equations can be adapted to allow for differences in preharvest sprouting damage.

Barley should have less than 130 g per kg of moisture for safe storage for 1 year, and less than 110 g per kg for safe storage for 5 years. Grains with more than 140 g per kg of moisture may heat and spoil rapidly. The moisture content of barley at 25°C will vary with relative humidity and at equilibrium will be 97 g per kg at 97% relative humidity, 135 g per kg at 70%, and 268 g per kg at 100%.

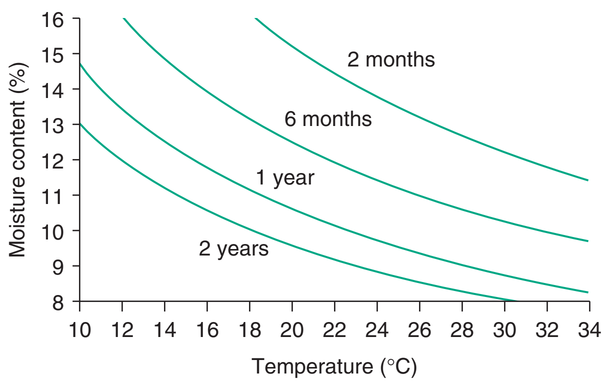

Figure 1 Safe storage of barley at different moisture contents and temperatures.

Dormancy

Some barley varieties have a brief period of dormancy immediately following harvest. This may be desirable in areas in which preharvest sprouting damage is prevalent. Malting of barley is usually delayed for some weeks or months after harvest to avoid dormancy. This may require barley to be stored for malting considerably more than 12 months after harvest, so that supplies are available for malting from the previous year's harvest until the new crop has emerged from dormancy. Dormancy of barley may be influenced by the variety (genetic factors) and growth conditions (environmental factors). Some varieties (when dried) with strong dormancy are treated (warm storage) to break dormancy to allow more immediate processing. Another strategy in some areas is to malt a minor variety with low dormancy immediately after harvest until preferred but more dormant varieties are ready. Some varieties are treated to break dormancy prior to processing. Dormancy of Triumph barley may be removed by warm storage immediately prior to malting.

Admixture

Barley varieties may germinate at different rates, complicating the malting of samples of mixed genotypes. This constraint means that malting barley storage requires more careful segregation of varieties than that of most other grain types. This adds to the cost of barley storage and transport. The same issues make the blending of barley parcels with widely differing specifications (e.g., protein content) to produce a target specification highly undesirable. Blending of malts after malting is the best way to ensure consistent malt specifications for the brewer. Planting of pure seedlots is a key approach to ensuring the harvesting of grain of a single variety. Testing of seed before planting and of plants in the field before harvest can be used to confirm the identity and purity of barley varieties. Testing of the harvested samples can be used to confirm these advance tests. Unfortunately, the analysis of the harvested samples cannot always be completed before the harvested grain is bulked or mixed in storage placing more importance on the preharvest testing. Varietal identity and purity have been analyzed based upon the analysis of seed proteins but methods based on deoxyribonucleic acid (DNA) analysis have increasingly been employed. The analysis of simple sequence repeats in barley DNA is widely used for this purpose. Analysis of identity and purity, and other characteristics influencing storage decisions may ultimately be determined by automated visual assessment using video and computer analysis.

Factors Influencing Storage Life

Moisture content and temperature are the key determinants of storage life. Barley storage is adversely affected by factors such as preharvest sprouting. Insect or microbial infestations may occur in storage but often originate in the field prior to harvest, only becoming obvious in storage. Storage treatments may be applied to protect the grain in storage. Insects may be managed using chemical agents, controlled atmospheres, or the addition of products based upon diatomaceous earth. Aeration of barley during storage can be used to control temperature and moisture distribution within the bulk.

Malting Quality

Malting quality requires that grains be of a suitable malting variety, have a high germinative capacity and energy, be clean and free from microbial or chemical contaminants, and not be an admixture. Brewers are increasingly concerned about possible contaminants at all of the steps in the production chain leading to beer. Beer consumers are often influenced by perceptions of the quality and purity of the product. Gushing is a specific problem of malting barley which has been linked to *Fusarium* infection. (Gushing is excessive frothing of the product.)

Feed Quality

Feed quality requires freedom from contaminants likely to detract from the feed value of the grain. Feed users also supply the food chain and aim to eliminate any undesirable chemical or microbiological contaminant.

Controlled-Atmosphere Storage

Storage of barley under controlled atmospheres can reduce the use of chemical pest control agents and eliminate residues. Protection of viability for malting requires special considerations when this approach is used with barley. High CO_2 concentrations may reduce oxygen levels to dangerously low levels for malting barley. Temperature and method of CO_2 introduction need to be managed for the success of this technology in barley.

Transport

Barley

Barley transport from field to maltings or feedlot may involve many steps. Transport from the harvester to primary storage or off-farm may be followed by repeated steps of transport by road, rail, and sea, and storage in a wide range of storage vessels. The control

of environment during transport may not always be as optimal as in the best fixed storages.

Malt

Malt is usually stored at very low moisture contents of ~4%. Removing more moisture may preserve the malt and reduce transport costs for malt that is transported large distances internationally. However, the energy cost of drying malt to very low moisture content may be high. Transport of malt to breweries involves many of the same issues as these associated with transport of the barley prior to malting.

Grading and Marketing

M J Edney, Canadian Grain Commision, Winnipeg, MB, Canada
M Brophy, Canadian Wheat Board, Winnipeg, MB, Canada

Introduction

Annual world barley production is expected to rise to more than 150 million tons (Mt) by 2011. It is anticipated that over 21 Mt of that production will be traded on the world market as either feed, malting, or food barley. The remaining production will be used in domestic markets for similar purposes. In either case, considerable effort in marketing and grading will be required to ensure that producers get paid appropriately while end users receive barley with the required quality and at a competitive price.

Malted barley, the major ingredient in beer, represents only a minor portion, ~25%, of total world barley trade, but it routinely offers the greatest return for producers. End users of malting barley, as well as barley for whiskey production and for food, are obliged to use at least some barley in their products. They also require the barley to have a unique set of quality characteristics. As a result, barley demand in these markets is more consistent and prices are higher.

The largest portion of barley production is used as feed on farms or sold in domestic markets, where there are limited demands on quality. Feed barley, especially in international markets, is often replaced by less expensive grains such as corn or wheat. Two specific markets, namely, Japan and Saudi Arabia, do not, for traditional reasons, substitute it with other grains, which makes them the two most consistent international markets for feed barley.

Marketing of barley consists of a series of activities that move grain from production to its end use. Marketing is a mechanism by which the conflicting demands of producers and end users can be reconciled. For barley with a given quality, producers look for the highest possible price, while end users want the lowest possible price. Barley marketing ranges from a simple exchange of commodities among neighboring farms to the complex use of handling companies and grain merchants on an international scale. It might require the use of intake points in the production area for collection of grain as well as export-handling facilities at ports for shipment. The silos and handling facilities at intake and export positions can be owned by private companies, large multinational grain companies, producer cooperatives, or by barley processors. Grain merchants are often involved in actual sales. They can be representatives of handling companies, independent marketing companies, or a state trading enterprise (STE).

Marketing is facilitated through the use of standards and grades that act as a marketing language through which buyers and sellers can communicate on the quality of barley to be delivered. Grades and standards sort barley into groups of similar quality. They indicate the expected performance of barley during processing and requirements for special storage, as well as any need for additional handling such as cleaning or drying. Sanitary factors such as the presence of contaminants can also be included while grading to indicate fitness of barley for human or animal consumption. Grades and standards are dynamic, changing with grain technology, weather conditions, and the changing demands of processors and consumers.

Marketing and grading mechanisms can vary considerably among the different exporting and importing countries. Local supply and demand as well as government involvement affect final arrangements.

Marketing

Marketing of barley is a complex process involving all the activities required to move grain from the field to the end user. It can involve three major components. The primary component is the exchange of barley for money. Another important component is arranging physical activities such as transportation or storage that are required for moving the product from field to the end user. Finally, marketing will include many facilitating functions such as standardization, financing, risk bearing, gathering of market intelligence, promotion, customer technical support, and after-sales service.

The marketing of barley begins with a producer's decision to grow grain for feed, alcoholic beverages, or food. First, there must be a local outlet available for delivery to the chosen market. Producers should discuss with these outlets, including local processors and handlers as to which markets are expected to be available at time of harvest, and any specific varieties that will be in demand. Only specific varieties can be effectively processed into alcoholic beverages or food and end-users will demand only those varieties. The feed industry is usually not concerned with specific varieties.

Environmental growing conditions will ultimately determine the appropriateness of a barley sample for malting or food processing compared with feed barley. Soil composition and fertility can influence barley quality, predominantly the protein content, while weather conditions during the growing season can have devastating effects on quality. Barley that has been downgraded due to poor growing or harvesting conditions can always be sold to the feed industry, given the right price. In contrast, it may be impossible to convert such barley into an end product that is acceptable to the malting or food industries.

Barley producers generally aim for the malting and food markets, when available, as they tend to be the most lucrative. However, occasionally, when price spreads are narrow, producers will sell top quality (malting or food) barley into feed markets in order to obtain quick cash and to avoid possible rejection of the barley later in the selection and/or delivery process. In order to be selected for malting or food, a barley must be deemed to have appropriate quality. Barley unsuitable for processing usually reverts back to the feed industry, but producers may store their barley and resubmit it for consideration if standards are relaxed due to changes in demand.

Barley that has been selected, be it for malting or food, can be destined for either domestic or overseas processors (Figure 1). In some countries, producers deliver their barley directly to domestic processors, but often barley is transferred to domestic processors through local grain intake points or to port facilities for export to overseas producers. In other countries, the barley is delivered directly to export facilities.

The decision on where to market feed barley depends on prices of the barley in local and international

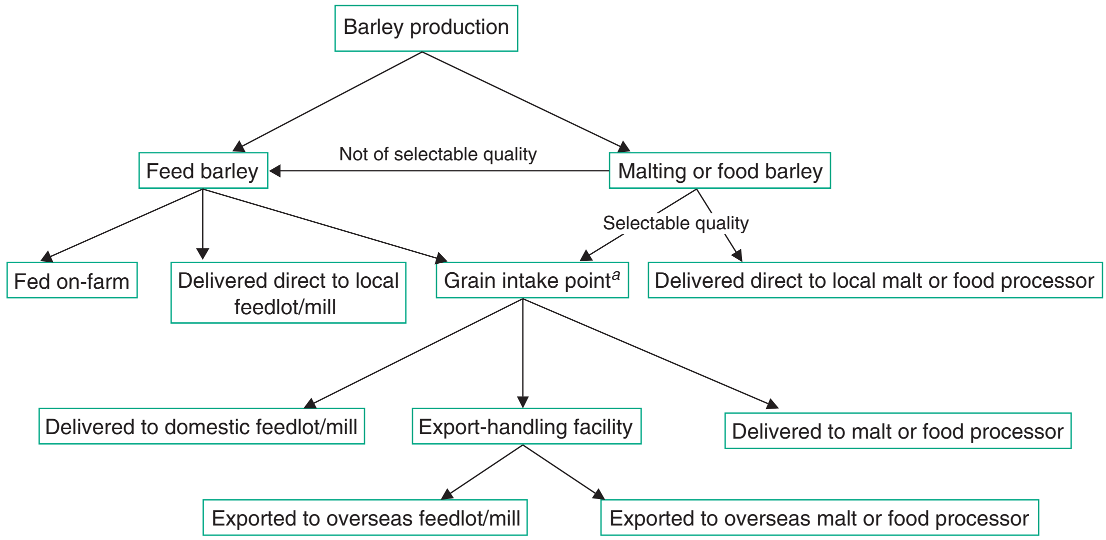

Figure 1 Flow diagram of delivery options of barley for feed and malting or food. [a] Deliveries of feed and selected barley can go directly to an export-handling facility at some locations.

markets. Prices depend on domestic supply and demand. The majority of feed barley is fed on-farm or sold to neighbors or local feedlots and/or mills. A second choice is delivery to a local grain intake point for transfer to more distant feedlots and/or mills or to export facilities. Once again delivery straight to the export facility is possible. In some countries, the final choice can be farm storage of the barley until a more appropriate time.

Grain Merchandizing

Grain merchandizing is a complex process involving grain-intake points, export-handling facilities, and grain merchants, including STEs. At grain-intake points, decisions have to be made on whether to store, condition, or blend delivered grains. Conditioning can consist of cleaning, separating, or drying the barley. In most cases, where intake points and export facilities are jointly owned, the barley is simply transferred to export facilities, where most of the storage, conditioning, and blending takes place.

Marketing of barley is not just a matter of a seller finding a buyer and agreeing on a price, although that is the extent of it in some sales. More typically, arrangements between seller and buyer include much more detail. In some cases, quality terms are on the basis of known standards or grades of the seller. However, buyers often stipulate their own specifications, especially for malting barley. In either case, specifications are included in the sales contract along with the agreed method for determining and documenting the quality delivered. In most cases, an independent testing agency is agreed upon by the parties. Other factors included in a sales contract can be adjustments and penalties for specifications outside of tolerances, shipping terms and demurrage clauses, and dispute-settlement clauses.

Contracts are often based on the templates of the Grain and Feed Trade Association (GAFTA) of the UK. GAFTA offers over more than one hundred different contracts to cater for the type of grain, the origin of grain, the units (imperial or metric), and many other variables. Much of the barley trade worldwide is carried out under GAFTA contracts. The quality specifications and tolerances can be specified in detail in the contract or they can be on the basis of fair average quality (FAQ) for the origin in question. The definition of FAQ must be agreed upon and will depend on the origin of grain plus the growing year.

Quality specifications are of less importance in the world market for feed barley, which is more supply-sensitive and competitive. Price is the compelling factor. World feed-barley trade is dominated by a small number of companies, and demand is concentrated in a limited number of countries.

Marketing of barley, in many cases, involves a long-term relationship between buyer and seller. Relationships involve market development activities, technical support, and customer service programs. Many grain-exporting countries have developed specific institutes to assist with these activities through educational and promotional programs. Examples of such institutes include the Canadian International Grains Institute and the Canadian Malting Barley Technical Centre in Canada, the US Feed Grains Council in the USA, the Home Grown Cereal Authority in the UK, and the France Export Cereals in France.

Grading and Standardization

Grading of barley is used to facilitate grain merchandizing through the use of uniform tests and terms. Grades are measuring sticks of quality, where quality is defined as a subjective property of a barley sample that indicates its usefulness or value to an end user. In simple transactions, such as those between neighbors or with local feedlots and/or mills, inspection of the product at the time of delivery may suffice in agreeing on the grain's value. In contrast, international sales require a set of specifications in order for buyer and seller to agree on a value – grain unseen. The grades act as a market language allowing producers, marketers, and end users to communicate. As a result, the marketing process is simplified and marketing costs are reduced.

Grades separate barley into groups that meet certain standards. All the grains within a group have similar, but not necessarily identical, quality. Grades and standards can indicate potential processing value of the grain, its nutritional value, as well as other factors that may affect the overall value of the grain such as a need to dry or clean a sample, or even the need for special storage conditions. Grades and standards can be based on visual appearance or more objective machine testing.

Standardization, or the use of grades and standards, has benefits for all involved in the marketing of grains (Table 1). Grades ensure that grains of equal value receive equal monetary compensation and that a high-quality product receives a premium that allows end users to communicate their needs to producers. Grades foster a more efficient price-discovery process; they can reduce costs of handling and transportation through the use of bulk-handling systems. Grades lead to consistency in processing and satisfied end users. Grades can also reveal clear variations in quality, indicating opportunities for improvement such as drying, cleaning, and special storage. Enforcement of grades can reduce sanitary hazards such as contaminated grain.

The number of grades cannot be exaggerated without increasing costs and thus negating advantages. The grades must be easily applied such that they do not significantly slow down the handling and transportation of barley. However, the methods must still be accurate and allow for uniform measurement. There cannot be absolute uniformity at any cost. A grade must identify enough of average production to be a meaningful category. The best test of any grade is the degree of its use by end users.

Grading to Determine Processing Potential

Barley must meet quality specifications in order to be acceptable for malting or, to a lesser extent, for processing as a food (i.e., tea, pearling, sochu (a barley liquor)). The factors considered in selecting a barley for malting (Table 2), the predominant use for selected barley, indicate how well the barley will process in the malt house. Factors identify barley that takes up water at a quick and consistent rate, germinates in a uniform manner, and is capable of producing a final product of acceptable quality. Of special interest is the need for varietal purity. Each variety malts slightly differently, and mixtures of varieties often do not malt to their full potential. Each malting barley variety has been bred specifically for malting, and acceptance of its potential is indicated by the variety's registration or listing on an official eligibility list, often maintained by domestic barley industries. Barley deemed unacceptable for processing as malt or food is reverted to the feed industry.

Barley selected for barley tea or pearling must also show specific characteristics in order to ensure

Table 1 List of advantages and disadvantages of using grades and standards

Advantages	*Disadvantages*
Maintain consistent pricing and ensure premiums for top quality product	Grading contributes to costs and advantages must outweigh this cost
Allows end users to communicate their needs to producers	Grading of grains can affect throughput at handling
Reduce handling and transportation costs through bulk handling	Quality is subjective – agreements on actual specifications can be difficult
Attract and keep customers through delivery of consistent product	
Reduce sanitary hazards	

Table 2 Examples[a] of grain characteristics that may be used in selecting barley for malting

Characteristic	*Desired quality*
Protein level	9–12% dry matter
Barley variety	Locally recognized malting barley variety
Varietal purity	>98%
Germination after 3 days	>95%
Falling number	>300 s
Rapid Visco Analyzer	>130 stirring number
Pesticide residues and mycotoxins	Minimal (according to national standards)

[a] Characteristics will vary among countries.

straightforward processing. Barley for pearling must have an appropriate endosperm texture to prevent kernel breakage, and kernel size must be uniform in order to ensure a consistent pearled product. Barley for tea must be of a desired variety and also show a consistent kernel size in order to produce a uniformly roasted end product. Similarly to malting barley, these characteristics are often ensured by offering varieties that are known to be acceptable to end users. Feed-barley end users often demand a barley with special processing characteristics. This is especially true when barley is rolled prior to feeding. Uniform size is essential if rolled barley is to be sufficiently cracked without production of excess fines.

Grading to Determine Overall Value

The overall value of barley, be it for feed, food, or malt, is determined by grading a barley sample's size, moisture, cleanliness, and appearance. Factors considered include kernel size and weight, presence of damaged kernels and appearance, as well as the presence of foreign matter such as other cereals, small seeds, and wild oats. The application of grades varies among countries, with some applying premiums and discounts for particular factors, while in others a series of parameters are used to determine a grade, and each grade is assigned an appropriate price.

Examples of grade specifications for a number of exporting countries are listed in Tables 3–7. The

parameters, as well as specifications for the parameters, vary among countries, reflecting differences in infrastructure, customers, and growing conditions.

Establishing and Analyzing Grades and Standards

The establishment of specifications for grades and standards can be difficult. Scientists and the trade tend to develop standards that are easily measured but not necessarily informative or accurate. Conflicts may arise between buyers and sellers, and compromises may form part of marketing negotiations. In the end, specifications must be indicative of value to the end user, otherwise the end users will not use the grades.

Table 5 Some of the EU intervention standards for feed barley

Characteristic	*Feed barley*
Test weight (kg hl^{-1})	62.0

Broken kernels (% by weight)	5.0
Overheated grain (% by weight)	3.0
Other cereals (% by weight)	5.0
Total foreign matter (% by weight)	12.0

Data from European Commission.

Changes in the preferences of consumers, the ultimate end users, have increased the pressures on the system. Marketing agreements have had to evolve and now often include more specific and tighter quality conditions. Marketers and end users have increased their reliance on grower contracts and identity-preserved systems in order to meet and document specifications. In some cases, documentation is required on the type of seed and variety planted and a history of pesticide use, as well as specific information on the nutrient content of the grain. The result is tighter control and a need to preserve the integrity of the product as it moves through the system. Such extra control leads to greater costs, with higher prices for end users but not necessarily better prices for producers.

Determination of a barley's grade is totally dependent on obtaining a representative sample for testing. At large grain-intake points and export-loading facilities, representative samples are obtained with automated equipment that takes samples from a moving grain stream. At smaller facilities, samples must often be obtained using manual probes of a lot at unload. Considerable documentation exists on proper sampling techniques.

Grades and standards are largely determined using objective, machine-based methods. Levels of protein

and moisture are measured using near-infrared technology, which can also indicate the processing potential of a sample for malting or even the nutritive value of a sample for feeding. Automated agitators and screens are used to determine kernel size distribution, although imaging technology can provide more information on size homogeneity. Imaging can also quantify damaged kernels, but this largely remains a visual task. Varietal purity is based on visual inspection with confirmation, often on a random basis, through more objective methods such as gel separation of proteins or deoxyribonucleic acid (DNA). Machine tests such as falling number and rapid visco-analyzer indicate any preharvest sprouting in a sample and thus its storability. However, a three-day germination test remains the only reliable method for ensuring a sample's germination potential. The single-kernel characterization system is used to identify barley with appropriate endosperm texture for pearling and further processing. It can also determine the homogeneity of a sample with respect to size, weight, moisture, and protein. Measuring pesticide and mycotoxin residues in a sample requires specialized lab equipment and is usually done only on a random basis unless specified. General appearance of a sample remains largely a visual process, but some countries rely on machine-based methods for quantifying grain color.

Specific Details for Some Major Barley-Exporting Countries

Australia

Australia is the leading malting-barley exporter and one of the major feed-barley exporters in the world (Table 8).

Traditionally, Australian barley has been marketed by an STE, but recent deregulation has allowed for increased private trading of barley. The boards, such as the GrainPool and the former Australian Barley Board (now ABB Grain Ltd.), have no monopolies on the marketing of barley domestically. Monopoly powers continue to exist, in some states, for the export of feed and malting barley, although additional changes could further reduce these powers.

Australian marketing agencies set the quality specifications (Table 3) of the various grades of feed and malting barley purchased from producers and apply price adjustments accordingly. These agencies work with the local storage and handling corporations (in some cases they are one and the same) to provide payments to growers, which reflect the quality of the barley delivered.

When exporting grain the marketing agencies trade according to the specifications agreed with the importer, and the quality standards may vary by contract. In most cases, the marketing agencies provide analysis of specifications, although independent private analyzers are used when required.

Canada

Canada is the second leading exporter of malting barley in the world and continues to export significant amounts of feed barley but not to the extent it did in the 1980s. A majority of barley production is used in the domestic feed industry.

Barley is marketed in Canada through the Canadian Wheat Board (CWB), an STE with marketing monopoly, which operates under government legislation. Domestic feed barley is exempt from the CWB monopoly and is, therefore, bought and sold on the open market. However, all other categories of barley must be marketed through the CWB. Thus, exports of feed, malting and food barley, and sales of malting and food barley to domestic processors must go

Table 8 World exports (million tons) of feed and malting barley by country (1997–2011)

	Feed barley			*Malting barley*

USA	0.8	0.6	0.6	0.2	0.2	0.2
Others	1.5	2.0	2.6	0.3	0.3	0.4
World total	12.7	13.7	15.2	4.1	5.9	6.4

Data from Canadian Wheat Board.

through the CWB. Export sales to international customers can be direct from CWB or indirect via approved accredited exporters, including Canadian and international grain trading companies.

Growers receive payment for feed, malting, and food barley delivered to the CWB based on official grades (Table 4) of the Canadian Grain Commission (CGC). The CGC, a federal government agency, determines, with industry consultation, the grade standards and provides third-party determination of grades. Official standards are not always applied to feed barley sold on the open domestic market, which often trades on specifications of the domestic feed industry.

In general, CGC grades are applied in international sales of Canadian feed barley. However, malting-barley exports are normally sold according to individual contract specifications as agreed with international buyers. Sales of malting barley and food barley to domestic processors can be according to official CGC grades.

European Union

The European Union (EU) is the largest exporter of feed barley in the world and the third leading exporter of malting barley. The EU is treated, for this discussion, as a single entity even though a number of countries contribute to barley production and market their barley independently.

Feed and malting barley are traded on a private basis in the EU. Open-market barley trades freely and finds its own price level on the domestic market as in most other countries. However, if domestic prices are higher than world prices, the EU can grant export refunds to allow domestic barley to be competitive in world markets. Feed barley is sold periodically in the domestic market or to non-EU markets from intervention (the internal EU-guaranteed floor price system) stocks using a tendering system.

The EU has a common set of minimum standards for feed barley (Table 5) that are applied to domestic intervention purchases as well as for all exports, either from intervention stocks or from the free market. Exports of malting barley are based on specifications in GAFTA contracts.

Russia/Ukraine

In recent years, Russia and Ukraine have emerged as significant exporters of feed barley. Barley is marketed in an open-market-type system, with the export of barley being handled by the private trade.

For internal trade, the State Committee of the Russian Federation for Standardization and Metrology (GOST) establishes grades for barley. Sellers and buyers conduct trade according to GOST standards (Table 6). Product specifications are analyzed and certified by the State Grain Inspectorate.

Exports are made on the basis of contract specifications negotiated between buyer and seller and agreed in the sales contract. GAFTA contract templates are often used to specify the agreed quality standard and method of analysis. Specifications are certified by the State Grain Inspectorate.

USA

The USA is a major exporter of feed barley. It also exports small quantities of malting barley.

US barley is marketed under an open-market system. Various private traders compete for supplies of barley and for export business. Prices paid to producers are determined at the intake point and are based on a series of discounts determined from analysis of the delivered barley. The majority of malting barley is now production-contracted by maltsters and brewers who often specify their own barley varieties.

In the USA, the Federal Grain Inspection Service (FGIS), a division of the Grain Inspection, Packers and Stockyards Administration (GIPSA), is responsible for grade analysis and, in consultation with industry, the setting of standards (Table 7) for barley. Official inspection and weighing of US barley is mandatory for export but not for domestic commerce. Inspection services, or official grade analysis, can be performed by private agencies that have been licensed by the FGIS.

Specific Details for Some Major Barley-Importing Countries

China (Malting-Barley Imports)

China is the largest malting-barley importer in the world. Until the mid-1990s, all malting barley imports were done through an STE, the China National Cereals, Oils and Foodstuffs Import and Export Corporation (COFCO). Recently, imports have been liberalized, and now end users and local trading companies from China are free to import barley directly and to conclude their own contracts, in terms of both price and quality.

Sales contracts can be based on GAFTA terms or on individual contract terms, depending on origin, seller, or importer/end-user preferences. They specify the exact quality specifications to be delivered. The State General Administration of the People's Republic of China for Quality Supervision and Inspection and Quarantine (AQSIQI) verifies the quality of all imported barley. Only barley imports with an AQSIQ certificate are released for distribution.

Japan (Feed-Barley Imports)

Japan is a major feed-barley importer in the world market. Imported feed barley has traditionally been the main ingredient used in the production of a special type of heavily marbled beef called Kobe beef. For this use, barley is steam-rolled before feeding. Feed barley is also milled into compound feeds for other livestock such as dairy.

Japan is one of the few countries in the world that still retain STE, the Japanese Food Agency (JFA), with monopoly powers for buying and importing barley. The JFA is responsible for purchase and distribution of barley, for both human and animal consumption. The JFA conducts regular calls for tenders from supplying countries. Tenders are usually based on the official standard quality grades used in the country of origin, which are familiar to the sellers and the JFA. The JFA does its own testing to verify the quality of all delivered barley. Imports from tenders go into the JFA's stock and are distributed to domestic end users at agreed prices. In this system, there are no negotiations, with respect to price or quality specifications, between individual end users from Japan and international traders.

However, in recent years, the JFA has allowed for simultaneous buying and selling (SBS). Although the JFA still administers them, SBS purchases allow for individual negotiations between Japanese end users and international traders. Each year the JFA approves the total tonnage of grain that can be imported under the SBS system.

Saudi Arabia (Feed-Barley Imports)

Saudi Arabia is the leading feed barley-importing country in the world. In recent years, imports have been fully liberalized and privatized, with local traders and feed mills working with international trading agencies to source their barley. The only government constraint is that all imported barley be dyed with a red colorant in order to distinguish it from the locally produced and heavily subsidized barley. Typically, the majority of the barley that is imported is fed as whole barley to sheep, goats, and camels by Bedouins. Feed mills are sophisticated and import bulk barley for use in their rations, given favorable prices. Contract terms have become quite flexible since market deregulation, but they normally conform to GAFTA contract terms. The major parameter for selling barley into Saudi Arabia is a competitive price.

Milling and Processing

M S Izydorczyk and J E Dexter, Canadian Grain Commission, Winnipeg, MB, Canada

Introduction

Barley is one of the most widely cultivated cereal crops that can provide valuable nutrients required by humans and domestic animals. Its high adaptability to various climates and growing conditions has led to worldwide production averaging 147 million ton (Mt) per year since the early 1990s. Barley has had three distinct end uses – human foods, alcoholic beverages, and animal feed – but patterns of its utilization have changed throughout history. Barley was grown in the ancient world mostly to provide food staples for human nutrition. In ancient Rome, for example, barley was used in bread making, while later it became more common in soup and porridge dishes, usages that have survived into present times. Drastic changes in consumption patterns in the Western world took place at the beginning of the twentieth century, when grains such as rice, wheat, and maize gained greater preference. The utilization of barley for food dropped drastically, except for barley used in the production of alcoholic beverages, especially beer. The world's use of malting barley for beer production significantly increased after the Second World War, but this trend reversed itself at the end of the twentieth century, especially in the West. The use of malting barley in Asia, however, continues to increase. Cultivation of barley for feed is a more recent development, but it has significantly exceeded other uses, and the

majority of barley production today is used for feeding animals.

Although barley has lost its earlier pre-eminent position in human nutrition, at least in industrialized countries, recent collaborative efforts in a variety of disciplines – such as medicine, nutrition, and agriculture – have elucidated the role of grains in prevention and treatment of many human diseases and revived interest in barley for food purposes. Current developments in processing barley and incorporating it in various food products stem from the many health benefits associated with certain components of this cereal. The food industry is now facing the challenge and opportunity to develop novel, palatable, attractive, and healthy barley-based products that will gain acceptance among consumers.

Composition of Barley Grain

Barley grain consists mainly of carbohydrates, proteins, and lipids (Table 1). Carbohydrates are major components, with starch being the principal constituent. Barley is known for its high content of total dietary fiber (~10–20%), and mixed linkage β-glucan has been shown to lower plasma cholesterol, reduce the glycemic index, and reduce risk of colon cancer. The nutritional value of other dietary fiber components – such as arabinoxylans, cellulose, fructans, galactomannans, and arabinogalactans – has not yet been thoroughly elucidated. Barley proteins are poor in certain amino acids, e.g., lysine and threonine, but considerable improvement of lysine content has been achieved with the development of high-lysine barley mutants. Barley grain contains some important lipids, such as tocols (tocopherols and tocotrienols), which posses some antioxidant properties. The concentration of α-D-tocotrienol, known to inhibit cholesterol synthesis in livers of experimental animals, is higher in barley than in other grains. A second cholesterol inhibitor, α-linoleic acid, has also been found among the barley fatty acids. The recently recognized involvement of antioxidant compounds in preventing the formation of carcinogens from precursor compounds has directed attention to such barley components as phenolic acids, phytin, vitamin E, proanthocyanidins, and catechins. Barley is also an excellent source of B-complex vitamins, especially thiamine, pyridoxine, pantothenic acid, niacin, as well as biotin and folacin. Elemental minerals occur in barley grain with concentration between ~2% and 4%. The major components are phosphorus, potassium, and calcium, with lesser amounts of chlorine, magnesium, sulfur, and sodium. Phosphorus is one of the most important mineral nutrients in barley, but up to 80% of barley phosphorus may be nutritionally unavailable because it is bound to phytic acid. This problem is being addressed by the development of low-phytic acid barley genotypes.

Table 1 Barley composition

Component	*Content (%, dry weight)*
Carbohydrates	78–83
Starch	60–65
Arabinoxylans	4.4–7.8
β-Glucans	3.6–6.1
Cellulose	1.4–5
Simple carbohydrates (glucose, fructose, sucrose, maltose)	0.41–2.9
Oligosaccharides (raffinose, fructosans)	0.16–1.8
Lipids	2–3
Proteins	8–15
Albumins and globulins	3.5–4.5
Hordeins	3–5
Glutelins	3–5
Minerals	2–3
Others[a]	5–6

[a]Barley also contains small quantities of B-complex vitamins, including thiamine (B_1), riboflavin (B_2), nicotinic acid, pyridoxine (B_6), and pantothenic acid, biotin, folic acid, and vitamin E.

Adapted from MacGregor AW and Fincher GB (1993) Carbohydrates of the barley grain. In: MacGregor AW and Bhatty RS (eds.) *Barley Chemistry and Technology*, pp. 73–130. St. Paul, MN: American Association of Cereal Chemists.

Chemical composition of barley is strongly influenced by both genetic and environmental factors. The presence or absence of the hull after harvesting, and the inherent starch characteristics, are the two fundamental genetic factors influencing barley composition. The hull or hull-less characteristic is established during development and maturation of the grain. In hull-less barley, the unattached, loose husk is visibly separated from the kernel during threshing; in hulled barley, the husk remains attached. Generally, hulled barley is chosen for malting, whereas hull-less barley has been used in animal feeds and shows better potential for incorporation into human foods.

The distribution of various chemical constituents is not uniform throughout the component tissues of barley grain, i.e., husk, pericarp, testa, aleurone layer, endosperm, and embryo (Figure 1). The husk and pericarp, the two outermost and protective tissues of the barley grain, consist primarily of cellulose, hemicellulose, lignin, and lignans – the major components of insoluble dietary fiber. The husk contains the highest proportion of minerals, followed by the embryo and the endosperm. Proanthocyanidins and catechins occur between the cuticularized layers of

testa. The embryo, which constitutes ~2.5% by weight of the barley grain, is rich in protein (34%), lipids (14–17%), and ash (5–10%), and is very rich in sugars (sucrose, 15%; raffinose, 5–10%; and fructosans). The cell walls of the scutellum are composed mainly of hemicelluloses and contain some phenolics, mainly ferulic acid. The thick walls of the aleurone layer (2–5 μm) are composed mainly of

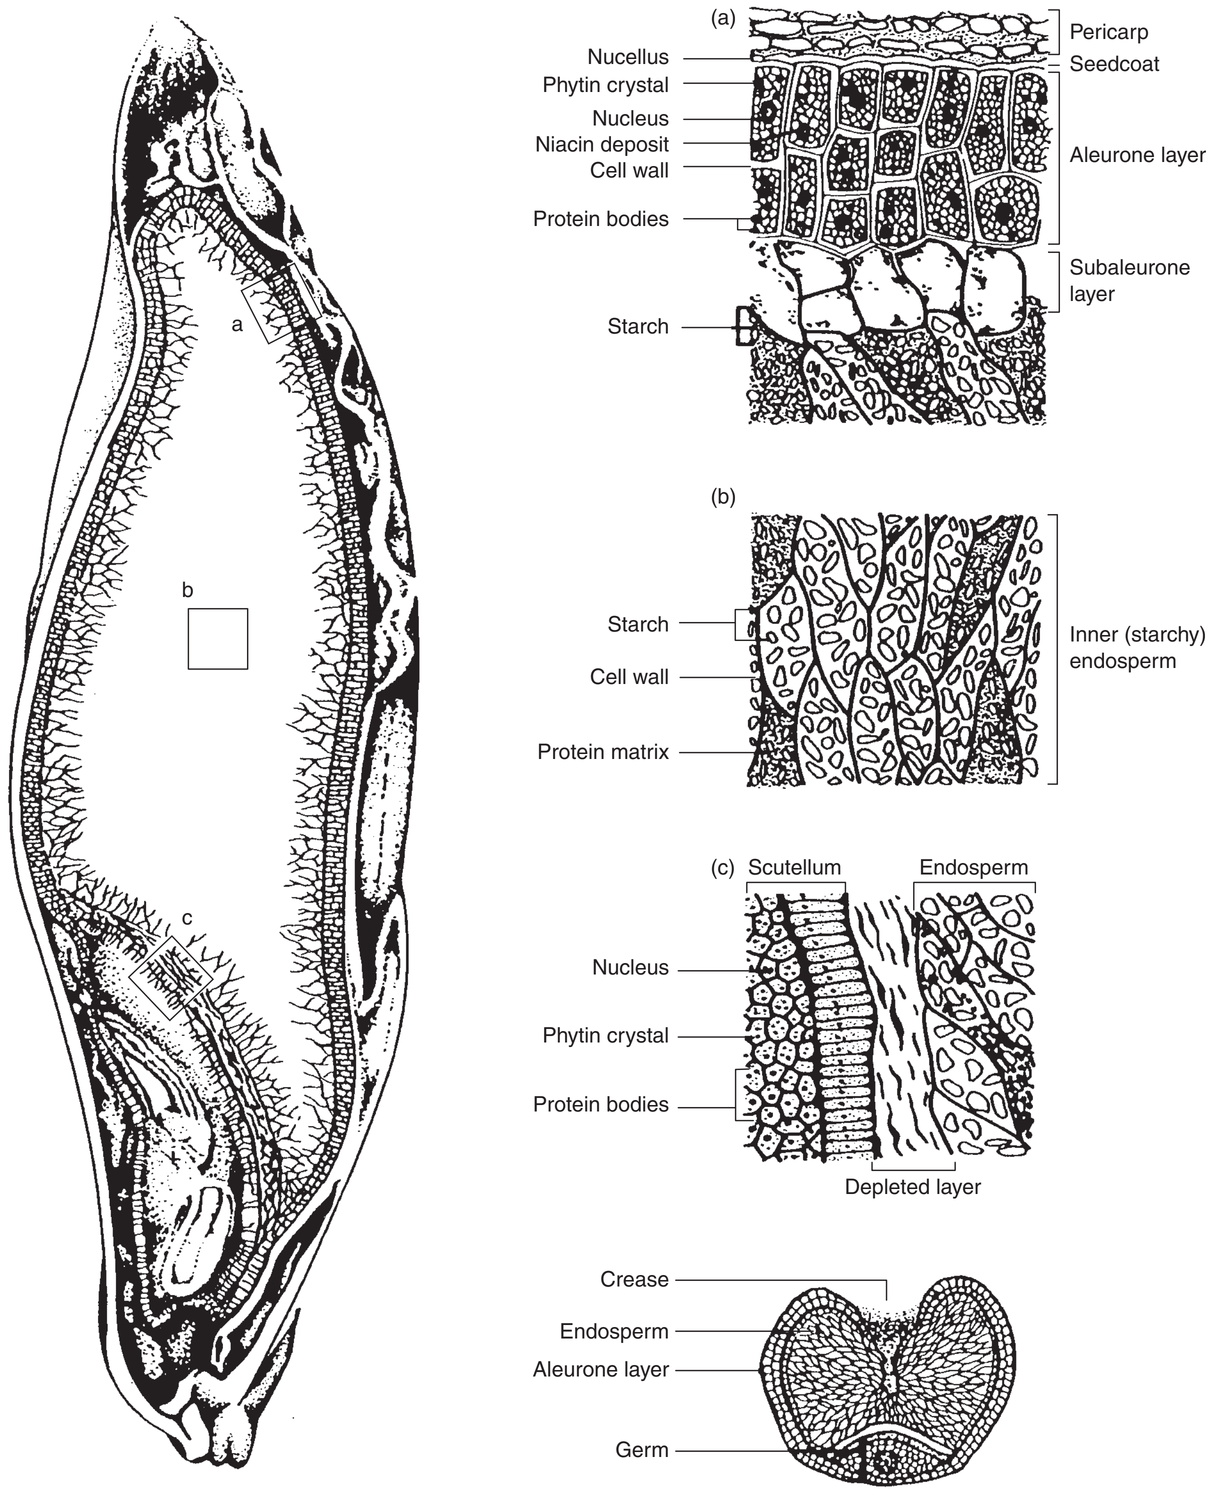

Figure 1 Structure of the barley kernel sectioned longitudinally (left) and transversely (right), with detailed bran layer (a), starchy endosperm (b), and embryo (c). (Courtesy of Fulcher RG and Wong SI.)

arabinoxylans (67–71%) and β-glucans (26%), and also contain phenolic acids. This tissue also abounds in proteins (17–20%), triacyl glycerol (20%), minerals, phytin, and sugars (including sucrose, raffinose, stachyose, verbascose, and fructans). Aleurone cells contain bodies called aleurone grains; these consist of globoid composed of phytins, and crystalloids composed of proteins and polysaccharides. Deposits of β-(1→3) glucans (callose) are found at the aleurone–subaleurone interface.

The starchy endosperm makes up ~75% of the barley grain. In the mature barley grain, starch, which constitutes ~80% of the endosperm, exists in granular form, with two distinct populations of large (A-type) and small (B-type) granules. The small granules account for 90% of the total number of granules, but only 10% of their total weight. Starch is composed of two polysaccharides, amylose (AM) and amylopectin (AP), with AP constituting ~75% of the starch in normal barley. Two single-gene mutations can alter the AM/AP ratio. When the genetic trait of waxy starch is present, starch contains 95–100% amylopectin. The other mutation increases the amylose content up to 40%. The AM/AP ratio in different barley genotypes (waxy, normal, and high amylose) has a significant effect on the *in vitro* digestibility of these starches, with the high-amylose starch being the least and waxy starch the most susceptible to α-amylolysis. However, the results of the *in vivo* studies are not yet conclusive. For example, when waxy barley starch is fed to rats, swine, or chickens, no increased digestibility is observed when compared with normal barley. The starchy endosperm also contains a relatively larger amount of proteins (~9% of the tissue) and smaller amounts of lipids, minerals, and nucleic acids. The cell walls of starch endosperm (2 μm thick) are built up mainly of mixed linkage β-(1→3), (1→4)-glucans (70%), and arabinoxylans (20%), with only small amounts of proteins, β-(1→3) glucans, and other polysaccharides containing galactose, mannose, and uronic acids. The presence of waxy or high-amylose genes in barley affects the carbohydrate metabolism in the grain, and waxy and high-amylose barleys are consistently higher in β-glucans than normal starch genotypes.

Barley Pearling

Pearling is one of the oldest practices of processing barley. Pearling is a process of abrasive scouring that gradually removes hull, pericarp, seedcoat, aleurone and subaleurone layers, and the embryo. One type of pearling machine consists of three to eight carborundum or emery stones, which revolve rapidly within a perforated cylinder. The hull and other fractions of the kernel are gradually rasped off by rubbing against the stones and the perforated cylinder. The time the kernel stays in the abrasion chamber determines the degree of abrasion. Depending on the pearling rate (degree), the process produces blocked (de-hulled) barley, pot barley, or pearled barley (Figure 2). Blocking removes only the husk. Removal of the next kernel layer, the pericarp, produces pot barley. Further abrasion, leading to formation of pearled barley, removes the seedcoat, aleurone, and subaleurone layers. The pearled barley represents usually ~40–50% of the grain, and may be adjusted as prescribed by the end use of the final product. Barley preferred for pearling should be uniform in kernel size and weight, plump, and free from discolorations. It has been proposed that two-rowed barley may be more suitable for pearling and milling because it is plumper and more uniform in kernel size and shape than six-rowed barley.

Pearling removes the components present in the outer layers of the barley kernel. Thus, the content of insoluble dietary fiber in pearled barley decreases with increasing pearling rates (Figure 3). The content of β-glucans, fat, protein, tannin, and phosphorus initially increases with increasing pearling rates, but declines after reaching optimum values between 15% and 30% decortication (Figure 4). In hulled barley, the hull and pericarp are usually present in the first

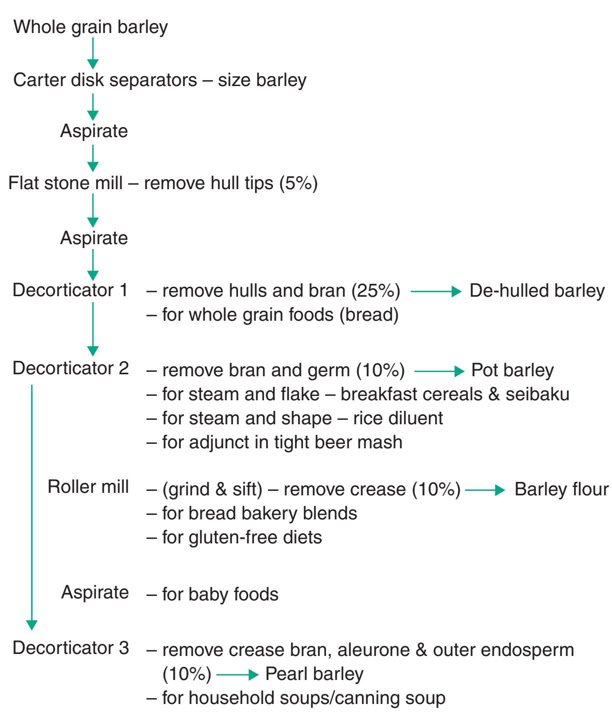

Figure 2 Diagrammatic representation of the processing of barley into various fractions. (Courtesy of Frank Sosulski, University of Saskatchewan, Saskatoon, Canada.)

0–11% pearling by-product fractions, whereas the germ and aleurone constitute the subsequent 11–25% fractions. Due to the presence or absence of hull, the constitution of pearling by-products may vary for hulled and hull-less barley. The pearling

(Reproduced with permission from Pedersen B, Bach Knudsen KE, and Eggum BO (1989) Nutritive value of cereal products with emphasis on the effect of milling. *World Rev. Nutr. Diet.* 60: 1–91.)

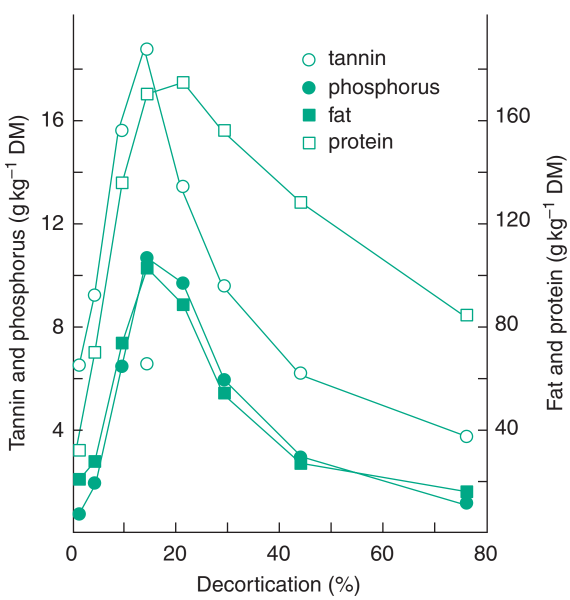

Figure 4 Relationship between degree of pearling (decortication) and the relative concentrations of tannin, phosphorus, fat, and protein. (Reproduced with permission from Pedersen B, Bach Knudsen KE, and Eggum BO (1989) Nutritive value of cereal products with emphasis on the effect of milling. *World Rev. Nutr. Diet.* 60: 1–91.)

by-products are potentially concentrated sources of bioactive components such as phytate, vitamin E (including tocotrienols), phenolic compounds, and insoluble dietary fiber. It has been shown that the pearling by-products of hull-less barley obtained at 20% pearling rate were enriched in tocols and contained 2.7–4.4 times more α-tocotrienols, α-tocopherols, and vitamin E activity than whole barley grain. Hence, pearling by-product is a nutrient-rich, health-promoting food ingredient. Utilization of pearling – by-products for making pasta (by substituting 50% of standard durum wheat semolina) resulted in a product that was darker than durum wheat pasta but had good cooking characteristics with regard to stickiness, firmness, and cooking losses. Because of the high dietary fiber (15.2–16.1%) and β-glucan (4.3–5.0%) content, barley-enhanced pasta may be considered as a healthy food product.

Pearled barley contains mainly the central endosperm of the kernel, enriched in carbohydrates (starch and β-glucans) and proteins. Examination of the amino acid and protein composition in 16 consecutive layers of barley grain has revealed that the albumin protein fraction decreases from the outer layer toward the center, whereas the hordein and glutelin fractions increase from the outer layers to the middle ones, and then decrease toward the center. The globulin fraction exhibits a homogeneous distribution throughout the whole grain. The content of glutamic acid and proline increases towards the center, but other amino acids decrease or do not change. The distribution of β-glucans in hull-less barley grain has emerged from an examination of pearling by-products (pearling fines) collected at 10% intervals during successive abrasion of barley kernels up to 30% of their original weight. The low β-glucan genotypes of hull-less barley have a greater concentration of β-glucan in the subaleurone layer, which declines slightly toward the inner layers. The high β-glucan varieties, on the other hand, exhibit evenly distributed β-glucan throughout the entire endosperm. Because of specific localization of β-glucans in the endosperm cell walls, pearled barley contains more β-glucans on the weight basis than whole barley (Figure 3).

Blocked or pot barley is usually subjected to further processing, such as milling, grinding, or flaking, before incorporation into food products, even though pot and pearl barley are used directly in various soup, stew, and porridge recipes. Pearling of hulled and hull-less barley to 45% and 40% rate, respectively, results in a barley product which can be used as a rice extender. The superior nutritive value of barley has increased the demand for barley rice extender among increasingly health conscious consumers. The process is straightforward, but requires a specific quality of

barley for trouble-free production and high-quality end product, which after cooking resembles white rice in color, shape, and texture. Waxy hull-less genotypes appear to have some advantages over covered or hull-less normal starch varieties because of their ability to pearl and split without breaking kernels or producing fines, and to produce desired color and texture after cooking.

Roller Milling

Barley does not have a long tradition of being fractionated by roller milling, and the fractions derived by this process have not yet been standardized in terms of quality, composition, or terminology. Nevertheless, barley has been roller-milled to obtain flour and bran, using wheat milling equipment (Buhler mill, Allis-Chalmers mill, and Miag-Multomat mill). It is often assumed that barley bran, like wheat bran, consists of testa and pericarp, germ, aleurone, and the subaleurone layers; its composition may differ, however, depending on the degree of pearling implemented prior to milling, and needs to be better defined. It is generally agreed that barley bran is brittle and difficult to separate from the endosperm by roller milling and, therefore, it increases the ash content and darkness of barley flour.

A wide range of flour yield, extending from 30% to 74%, has been reported for roller-milled barley. Roller milling of barley usually involves several break passages, sizing passages using corrugated rolls, and reduction passages with smooth frosted or corrugated rolls. Short duster passages, which utilize impact to separate starchy endosperm from the endosperm cell wall material, facilitate flour release. The number and sequence of passages in a mill affect the yield and composition of milling fractions. The Buhler laboratory-scale milling flow shown in Figure 5 consisted of four break (B), three sizing (S), two reduction (R), and four shorts duster (SD) passages. Following B4, the coarsest product after sifting ($>600\,\mu m$) was passed through the shorts duster (SD2) and the coarse material collected over screens was designated as "bran." For barley samples pearled to $\geq 20\%$, this material is predominantly derived from endosperm cell walls rather than from outer coverings (pericarp, testa, aleurone, and subaleurone). Therefore for roller-milled pearled barley, the term "bran" may not correspond morphologically with bran as traditionally defined in wheat milling.

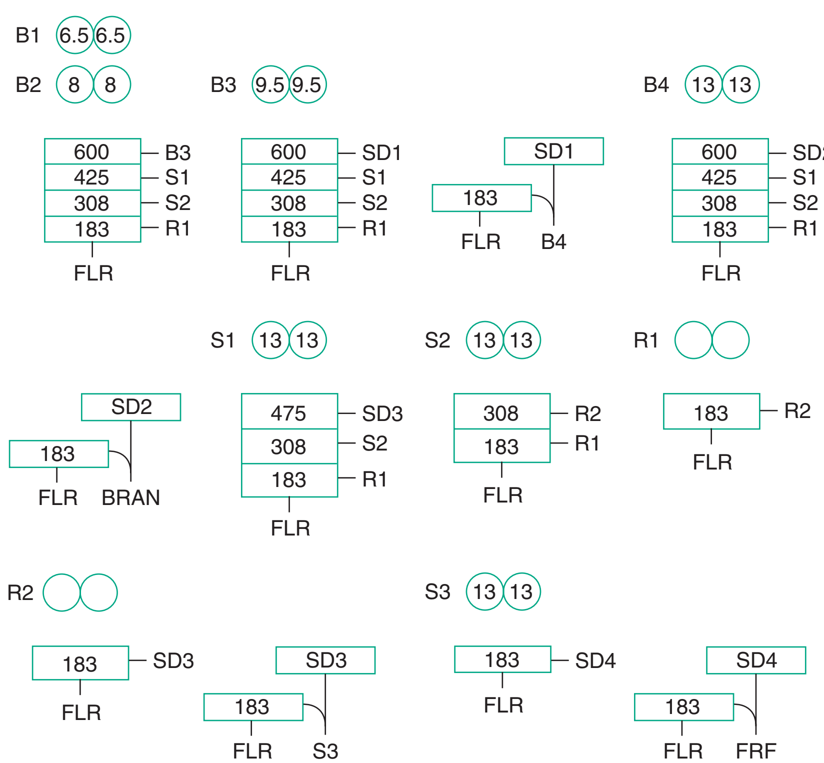

Figure 5 Roller milling flow for barley. B = break passage; R = reduction passage; S = sizing passage; SD = shorts duster; FRF = fiber-rich fraction. Numbers on roll symbols indicate corrugations per centimeter. Numbers on sieves indicate aperture in μm. SD screen has 140 μm aperture. (Reproduced with permission from Izydorczyk MS, Dexter JE, Desjardins RG, Rossnagel BG, Lagassé SL, and Hatcher DW (2003) Roller milling of Canadian hull-less barley: optimization of roller milling conditions and composition of mill streams. *Cereal Chemistry* 80: 637–644.)

Coarse material derived from SD4 following S3, which would be designated as "shorts" (fine bran from reduction system) in wheat milling, originates mainly from endosperm cell walls regardless of whether barley is pearled before milling. This fraction, therefore, may be designated more accurately as a "fiber-rich fraction" (FRF) rather than shorts. Straight grade flour is obtained by combining all break, sizing, reduction, and SD streams.

One of the most important factors influencing flour yield is barley genotype or, more specifically, the interrelated contents of β-glucan and starch. The high β-glucan genotypes, with waxy or high-amylose starch characteristics, may contain between 3% and 10% less starch than the low β-glucan varieties with normal starch characteristics. The high β-glucan barley genotypes yield, therefore, significantly lower amounts of flour but higher amounts of "bran" and "FRF" than the latter (Figure 6). High β-glucan barley flour has a higher proportion of large particles (150–250 μm) than of small ones (<105–150 μm), whereas the opposite is observed for low β-glucan barley. It appears that the endosperm cell walls of high β-glucan barley resist particle-size reduction during the milling process, which leads to lower flour yield and a higher proportion of large particles with adhered starch granules. Due to the plasticity of the thick endosperm cell walls of the high β-glucan genotypes, it is difficult to obtain clean separation of starch granules and other endosperm cell components from the cell wall material using successive break and reduction passages as in wheat milling. Impacting between grinding passages is necessary to optimize the process. Flour derived by impacting is also superior in color compared to flour produced by reduction grinding. Other preprocessing practices, such as tempering and pearling, may also affect the yield of milling fractions, their particle-size distribution, and composition (Table 2 and Figure 7). Today, the interest in obtaining better separation of starch from the cell wall material stems not only from the desire to obtain higher yields of whiter barley flour, but also from the demand for pure and highly concentrated barley fractions enriched in β-glucan and/or other bioactive nutrients.

Roller milling of barley has potential to fractionate the grain into various streams with unique composition and functionality. For example, waxy hull-less barley was fractionated using a Miag-Multomat roller mill equipped with three sets of break rolls and five sets of reduction rolls into six milling fractions: flour (obtained by combining the first break flour through the fourth middling), fifth middling, red dog, reduction shorts, break shorts, and bran. Among the milling fractions, the fifth middling, red dog, and reduction shorts were highest in total tocol concentration

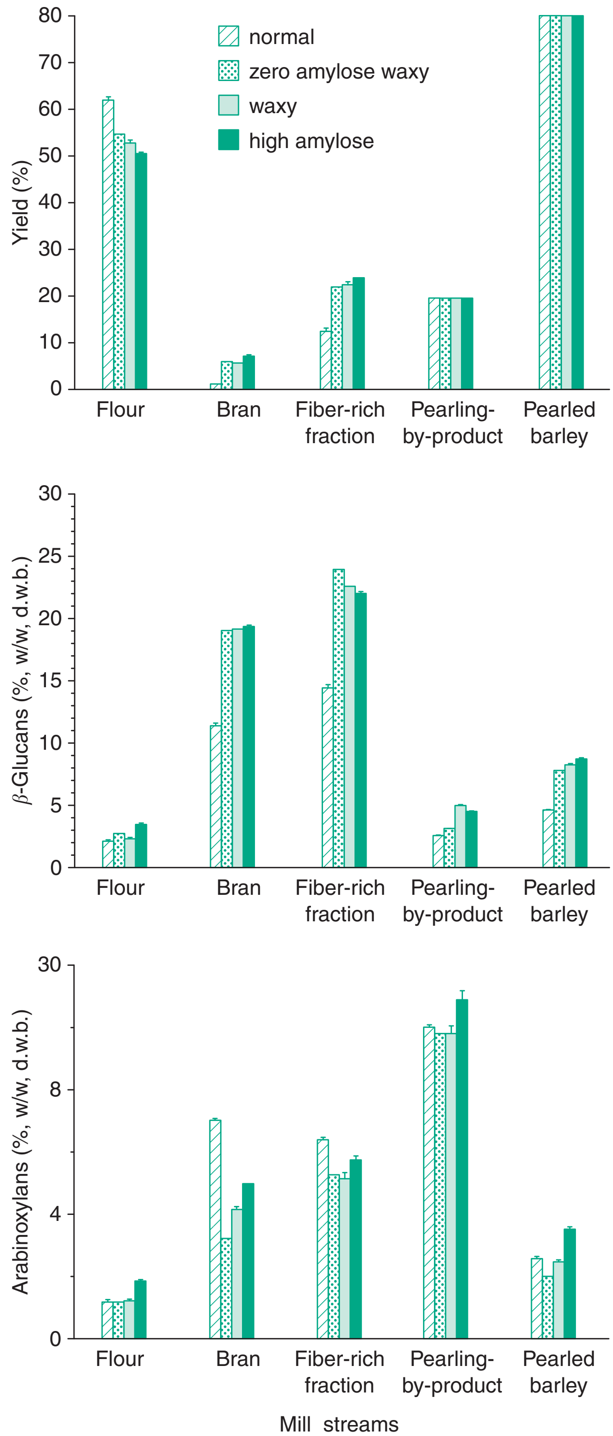

Figure 6 Yield (unpearled barley basis), β-glucan content, and arabinoxylan content of milled products from milling of hull-less barley genotypes. Barley was pearled 20% prior to milling. (Reproduced with permission from Izydorczyk MS, Dexter JE, Desjardins RG, Rossnagel BG, Lagassé SL, and Hatcher DW (2003) Roller milling of Canadian hull-less barley: optimization of roller milling conditions and composition of mill streams. *Cereal Chemistry* 80: 637–644.)

(Table 3). In another trial, where hull-less barley was pearled (20%) prior to fractionation in a Buhler laboratory mill, several nutritionally valuable milling fractions were obtained (Figure 6). β-Glucans and arabinoxylans from endosperm cell walls were highly concentrated in the FRFs obtained from the reduction system. For high β-glucan genotypes, yields of more than 20% (whole barley basis) of FRFs with β-glucan content of over 20% were obtained. Arabinoxylans, although especially concentrated in pearling by-products (10–12%), still constituted a considerable portion (~6%) of the FRFs.

Barley milling fractions have performed well in several baked products. Replacement of 20% of wheat flour in quick bread by both waxy and nonwaxy barley break flour or bran did not significantly affect loaf volume and produced a smooth attractive top crust surface and slightly softer texture of bread. Substantial increases of the total dietary fiber and β-glucan contents in bread have been obtained when fiber-rich barley milling fractions were blended with wheat flour. Satisfactory loaf volume and crumb structure can be achieved by choosing appropriate baking procedures, protein content in wheat flour, and/or

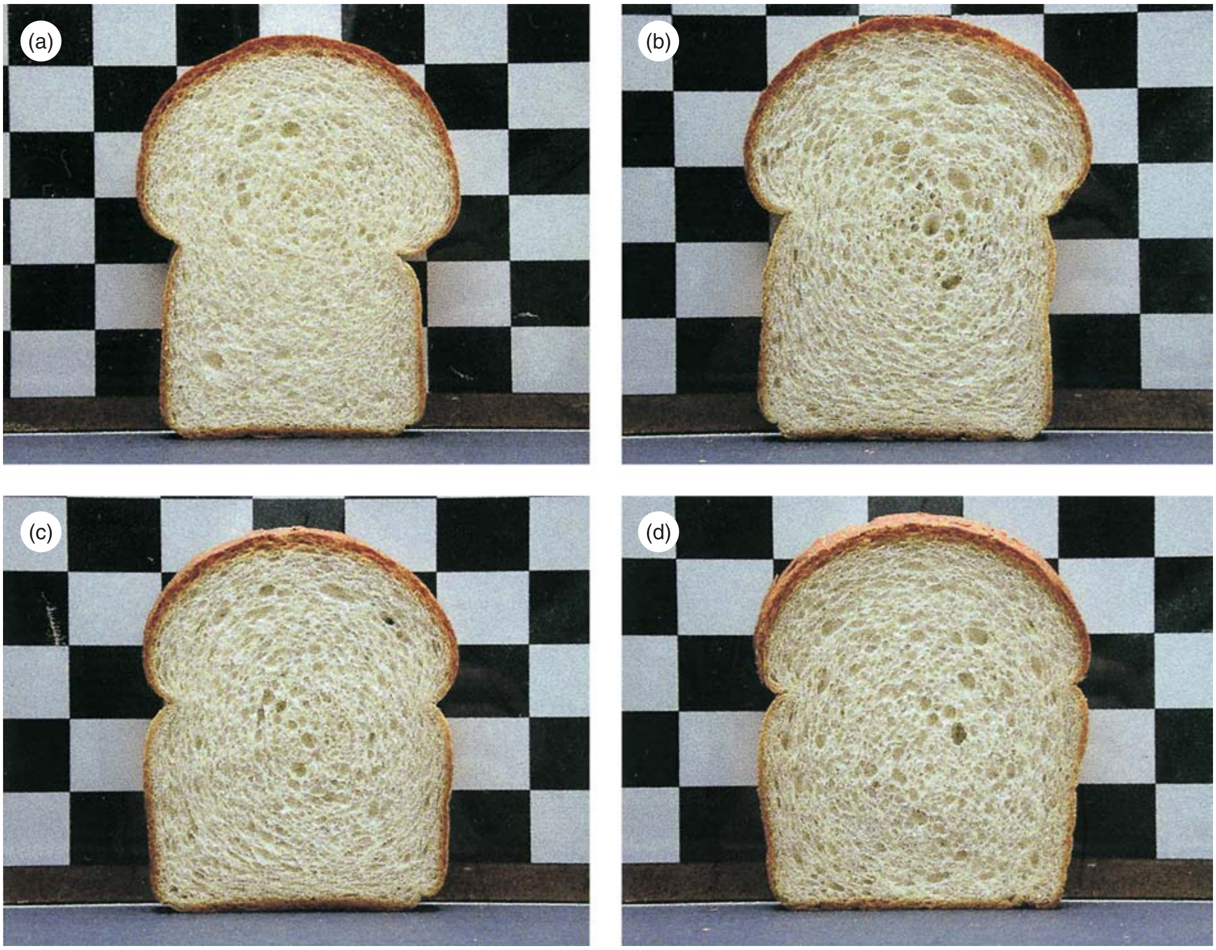

Figure 8 Effects of addition of fiber-rich barley fraction (15%) to wheat flour: (a) control wheat bread (CWRS, 14.5% protein); (b) wheat bread fortified with fiber-rich fractions from zero amylose; (c) high amylose; and (d) waxy hull-less barley. Bread baked according to the sponge and dough procedure.

enzymes (Figure 8). Fiber-enriched biscuits, sugar cookies, and muffins can also be produced with a waxy, hull-less barley milling fraction. Addition of barley flour (20–40%) to either white salted or yellow alkaline noodles gave products with acceptable appearance, with only a slight decrease of brightness and yellowness of the noodles. It was also shown that modification of noodle texture can be achieved by

incorporating barley flour with altered starch characteristics; for example, addition of waxy barley flour produces softer, less chewy white salted noodles, whereas the addition of high-amylose barley flour results in firmer and chewier noodles.

Milling and Sieving

Another approach to obtaining barley fractions rich in β-glucans involves milling of de-hulled barley, most effectively by an abrasion mill, and sieving the ground material through a series of sieves with openings of 45, 147, and 75 µm (Figure 9). The resulting fractions, especially those with particles >147 µm, may contain, depending on the variety, between 18.6% and 22.5% total β-glucan, which amount to 2.7–4.3 times enrichment of the original contents. This method, however, yields relatively small amounts of the β-glucan-enriched fractions (2.1–4.5%). The sieving process can be substantially shortened by implementing repeated sieving through only one type of sieve (150 µm), but the β-glucan enrichment in this case is only doubled.

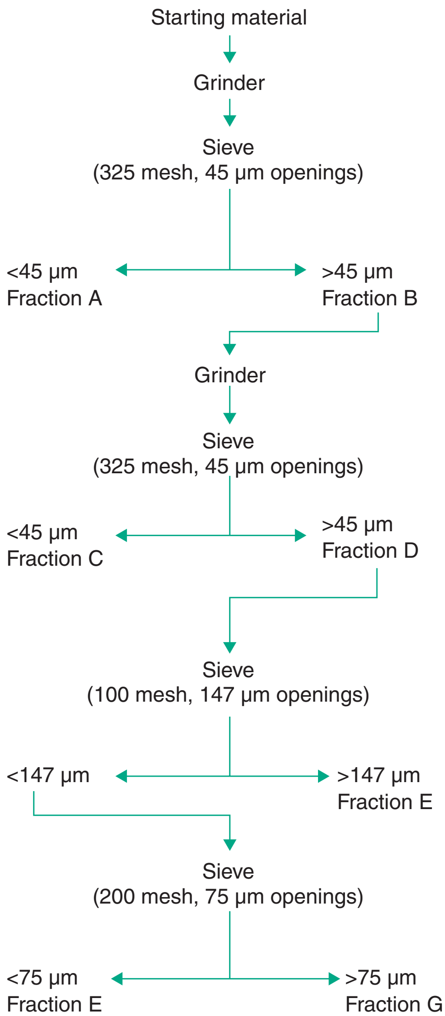

Figure 9 Milling and sieving procedure for barley to separate fractions by size. (Reproduced with permission from Knuckles BE, Chiu MM and Betschart AA (1992) β-Glucan-enriched fractions from laboratory-scale dry milling and sieving of barley and oats. *Cereal Chemistry* 69: 198–202.)

β-Glucan-enriched fractions can also be obtained when barley is pin- or hammer-milled and fractionated by air classifier and sifters. Coarse fractions obtained by these procedures are particularly rich in bioactive components and contain 37–45% total dietary fiber, including 16–18% β-glucan, and up to 82 µg g^{-1} total tocols. Bread in which these barley fractions replaced 20% of the standard wheat flour contained 4.2 times the total dietary fiber, 7.6 times the total β-glucan, and 80% of the total calories compared to the control. The bread was judged acceptable by sensory panels, although loaf volume was reduced and color was slightly darker than the control. Pasta in which fiber-enriched barley fractions replaced 20% or 40% of wheat semolina provided 5.4–10.4 g total dietary fiber per serving; it too had acceptable sensory qualities but was darker than the controls.

Air Classification

Application of air classification to barley also has potential for generating unique fractions enriched in specific components, and this technique should be explored and developed further, especially in light of current interest and demands for specific and functional grain fractions. Interest in using air classification to separate barley flours stemmed initially from the desire to develop nutritious high-protein fractions for food uses. Subsequent attempts at air classification of malting barley and barley flour were aimed at producing low-fiber, low-protein starchy flours with amylolytic activities, which are of special interest to the brewing industry. Recently, a method of preparing high soluble fiber barley fractions has been patented. The method involves a pin-milling step, followed by particle-size classification at 35–50 µm openings to separate the size-reduced flour into a starchy fraction and a fiber-enriched fraction with 1.2–5 times concentration of soluble dietary fiber compared to the original fiber level.

Air classification of waxy, regular, and high-amylose barleys has also been conducted with a view to obtaining fractions rich in large starch granules. Barleys were pin-milled to obtain meals passing through a 53 µm screen and fractionated into coarse and fine fractions by two passes at a vane setting of 15 µm and one at 30 µm (Figure 10). The first two fine fractions (F1 and F2) were protein rich and contained mostly small starch granules. In all three barleys,

air classification separated large starch granules from the small ones and concentrated them in the third fine fraction, F3. Most of the β-glucan in the ground barley appeared in the coarse fractions. The greatest enrichment of β-glucan was achieved in the third pass through the air classifier; the β-glucan contents were 23.8%, 13.1%, and 21.8% in C3 compared to 7.2%, 5.9%, and 7.8% in the whole grain for the waxy, normal, and high-amylose barleys, respectively. The yields of β-glucan-enriched fractions ranged from 7.6% for waxy and 10.4% for normal, to 20.9% for high-amylose barley.

Successful separation and concentration of grain components via air classification depends on such parameters as particle size distribution and fat content of the material to be air-classified. Substantial enrichment (62%) of β-glucan for air-classified high β-glucan barley variety Prowashonupana (originally containing 17–19% β-glucan and 6% fat) was obtained when de-fatting was conducted before processing. Parameters such as β-glucan content in barley, presence of hull, and starch characteristics may also affect the effectiveness of air classification. Further optimization of the process is required in order to obtain fractions concentrated in target component and to reduce the costs associated with power consumption.

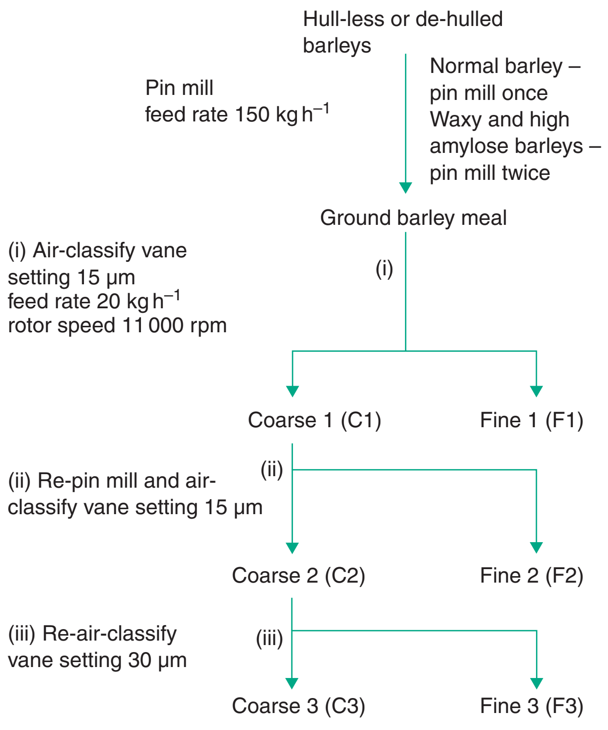

Figure 10 Diagrammatic representation of the procedure used for pin milling and air classification of barley. (Reproduced with permission from Vasanthan T and Bhatty RS (1995) Starch purification after pin-milling and air classification or waxy, normal, and high-amylose barleys. *Cereal Chemistry* 72: 379–384.)

Other Processing

Other forms of processing of whole or ground barley have also been developed. The treatments may vary from simple cooking and drying of whole grain, to hydrothermal treatments, to even more sophisticated extrusion cooking or infrared heating. These more contemporary processing methods aim primarily at improving nutritional value of barley, and at creating more shelf-stable and convenient barley-based food items/ingredients which can be easily consumed and/or incorporated in various food products. The processing of raw barley into products resembling traditional bulgur involves hydrating the whole grain to a moisture content between 45% and 70% by adding water and cooking the grain at temperature ranging from 60°C to 150°C. The temperature and time of this cooking step is important for obtaining optimal nutritional and functional properties of the final product. Following the cooking step, the grain is cooled and either dried or flash-frozen. If hulled barley is used for the production of bulgur, the grain has to be de-hulled after the drying step. Utilization of hull-less barley varieties eliminates this necessity. A cooked and dried grain product may be cracked, milled, or ground into flakes, granules, or powder and used as a ready-to-eat snack or cereal or further processed. Such processed barley may contain lower amount of vitamins, but can be an excellent source of dietary fiber. Increased water solubility, water binding, and adhering properties of this product improve its functionality and expand its potential as a multipurpose ingredient.

The hydrothermal processing of whole barley grain is shown to effectively degrade phytate (*myo*-inositol hexaphosphate) and, therefore, to increase the content of free *myo*-inositol (an important nutrient for infants) and the bioavailability of minerals such as phosphorus, calcium, iron, and zinc in barley. The treatment, comprising two wet steeps of barley grain in lactic acid solution alternated by dry steeps at elevated temperatures (45–70°C), and followed by successive drying (80°C), is thought to activate phytase, the endogenous enzyme which degrades phytate to free *myo*-inositol, and inorganic phosphate. Hydrothermally processed barley can be used in the manufacture of infant formulas or other applications such as gruels, flakes, or muesli products. Hydrothermal treatment is also used to reduce lipid oxidation during processing and storage of barley.

Another process aimed at improving the nutritional value of barley is extrusion. Extrusion cooking of high-amylose barley can facilitate formation of resistant starch in the extrudate. Resistant starch acts like dietary fiber in the gastrointestinal tract, resisting

digestion in the small intestine but undergoing fermentation in the large intestine, and resulting in formation of short-chain fatty acids (SCFAs), which are protective to colon mucosa. Formation of resistant starch increases the amount of total dietary fiber in barley after extrusion. Depending on the extrusion conditions (temperature, screw speed, and moisture content), desirable modification of other barley components may also take place during the process, including partial solubilization of β-glucans and formation of nondigestible oligosaccharides, thus improving the content of soluble dietary fiber in barley. Optimization of the process is necessary, however, to minimize vitamins losses. Another advantage of extrusion processing is improvement of palatability and technological properties of barley products. Due to good textural properties of barley extrudates, they may be consumed directly, used in breakfast cereals or as additives to other food products.

Malting

L MacLeod, Barrett Burston Malting, Richmond, VIC, Australia

Introduction

Malting is the term used for the preparation of a brewing raw material, employing a controlled germination of grain in moist air. Barley is the preferred grain for malting; however, other grains such as wheat, rye, sorghum, triticale, or oats may be malted and subsequently used in brewing, distilling, or food production. Barley is the most common cereal used for the production of malt for brewing since it has a high starch to protein ratio and adhering husk that

contribute to the economic yield and ease of processing in brewing and produces the characteristic flavors associated with malt for this purpose.

Malting aims to convert or modify the physical structure of the barley grain and allow synthesis or activation of a series of enzymes such that the final product, malt, is more readily used in the next stages of brewing, distilling, or food manufacture.

During the malting process, hydrolytic enzyme production and/or activation is maximized leading to cell-wall degradation and protein solubilization with minimal starch breakdown. In order for this to occur, malting aims to both accelerate germination and retard embryo growth, essentially conflicting activities. Any shoot or root growth produced during the malting process is physically removed from the final product prior to storage and delivery and therefore minimizing embryo growth reduces losses incurred in the process.

The final product of malting, malt, physically resembles the original barley grain but is friable when crushed, revealing the complex biochemical changes that have occurred during the malting process.

Barley Grain Structure

For the purpose of understanding the malting process, the barley grain can be divided into several major components: the embryo, the endosperm, the scutellum, the aleurone, and the husk (Figure 1).

The embryo is the living or metabolically active part of the grain. The husk covers the whole grain structure and consists of two parts – the lemma on the dorsal side of the grain (which is normally extended into the awn) and the palea on the ventral side. In most malting barley varieties, the husk is fused to the testa at maturity. The husk acts to protect the grain from infection during development and as such is relatively water resistant. In intact grain where the husk has not been damaged during cropping or harvesting, water enters the grain and the embryo through the micropyle. It is the embryo that contains the shoot and root primordia, which will grow during germination.

The endosperm is the initial source of stored nutrition to fuel seedling growth prior to photosynthetic nutrient production. The majority of the endosperm tissue is not metabolically active and consists of large cells without nuclei packed with starch granules embedded in a matrix of storage proteins (Figure 2).

The scutellum is a shield-like structure that divides the embryo from the endosperm. It plays a role in both the degradation of the starchy endosperm and the nutrition of the embryo. The aleurone in barley consists of three layers of cells, which surround the endosperm. These cells are responsible for the production or activation of the key hydrolytic enzymes that will be produced during the malting process.

Evaluation of Barley for Malting

Barley for malting must be of high viability, low dormancy, and uniform germination to produce a homogeneous malt product. Both two- and six-row barleys can be used for malt production and their unique quality characteristics make them suitable for a range of malt products. Barley is generally processed into malt in batches of single pure varieties. This ensures uniformity in processing.

Structural grain characteristics such as grain size and shape, endosperm density, cell-wall thickness, and husk content all may affect malt homogeneity.

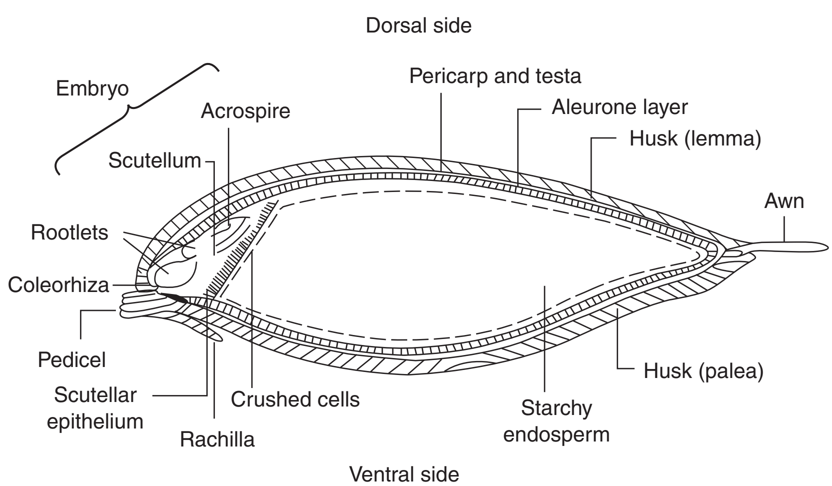

Figure 1 Major components of a barley grain.

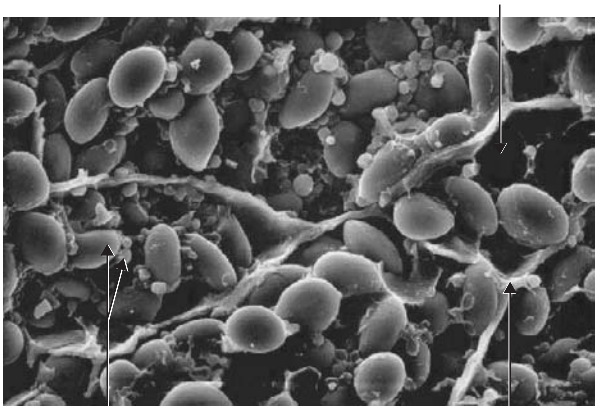

Figure 2 Endosperm tissue.

Malting barley should be of low protein and high starch content to maximize the potential for extract yield in the brewery. Extract is a measure of the amount of sugars extracted from the grain during the brewing process. The amount of sugars extracted is directly related to the level of alcohol produced and thus the value of the product in brewing and distilling. Protein levels must not be too low as proteins serve four basic functions in brewing. They are the origin of enzymes that catalyze the complex biochemical reactions involved in turning barley into malt and malt into wort. They are required for yeast nutrition; they contribute to foam and are involved in the flavor development that malt contributes to beer and whiskey.

Barley received for malting is cleaned by passing over a series of shaking screens with differing slot sizes to remove foreign material such as stones, nonbarley grains, and weed seeds. Broken grains, chaff or straw, and dust are also removed in this way and with aspiration. The cleaned sample is assessed for grain size, total nitrogen, and moisture to determine its suitability for producing quality malt. Critical tests for malting barley, however, are those that determine the viability, dormancy, germinative energy, and water sensitivity of the grain. These tests are carried out on every load of barley prior to processing.

The Malting Process

The malting process can be divided into three key stages: steeping, germination, and kilning. In the first stage, steeping, the acquiescent grain imbibes water and hydrates the embryo and endosperm. In the second phase, germination, enzymes are synthesized, activated, and mobilized, and the embryo begins to develop. In the final stage, kilning, grain growth is halted using a heat treatment (kilning), which dries the grain to constant and low moisture for storage.

Steeping

Harvested barley grain is generally stored at a moisture level between 10% and 15%. Storage of grain at this moisture level avoids mold growth and germination loss. Barley is generally processed into malt in batches, which may vary in size from 2 to 400T. The grain is cleaned and graded to remove foreign seeds, stones, straw, small and broken kernels, and dust prior to entering the steep vessels.

During steeping, barley is immersed in water to raise the moisture level to ~42–47%, which will allow the grain to germinate. The process also washes the grain removing any remaining loose debris and dust.

The embryo is the major living part of the grain and imbibes water rapidly through the micropyle while the endosperm (nonliving tissue) is hydrated by osmosis. Steeping aims to achieve a rapid and even uptake of water and oxygen in order to stimulate the embryo to respire and initiate hormone activity. The respiration of the embryo produces heat and carbon dioxide. Once the embryo is hydrated and metabolized, it is important to achieve a full and even distribution of water throughout the endosperm to produce a consistent quality in the malt.

Steeping involves a series of 2–4 immersions in temperature-controlled water, each followed by an air-rest period where the water in the steep is drained from the grain. The immersions allow the embryo to absorb water and the air-rest periods allow the water to be distributed into the nonrespiring endosperm. Steeping regimes are determined by plant design, barley characteristics, and condition and target malt specifications.

The steep vessels can take a number of forms (Figure 3a), but are generally either cylindroconical or flat-bottomed tanks. Design of steep vessels should ensure that hydrostatic pressure is not deleterious to grain health and this generally limits batch sizes to less than 100T in cylindroconical steeps.

In all cases the vessels should be well aerated with good water, temperature control between 12°C and 25°C, and efficient carbon dioxide removal. Aeration should be vigorous allowing a good rolling movement of the grain mass to optimize oxygenation and temperature control and removal of carbon dioxide (Figure 3b). During steeping, the embryo produces enzymes, which break down embryonic starch, initiating shoot and root growth. Hydration of the

Figure 5 Steeped grain spread on the floor for germination.

scutellum and aleurone initiates hormone (gibberellic acid) production, the catalyst for hydrolytic enzyme production. In some cases in commercial production (when permitted by customer specifications) exogenous gibberellic acid (GA3) can be added to mimic or increase the effects of the naturally produced hormone. Exogenous GA is usually added either during transfer of the grain from steeping to germination or early in germination when the grain bed is turned.

At the end of the steeping, the grain should be evenly and fully hydrated with a high (%) chit count. Hydration is commonly determined by measuring the moisture content of the grain; however, this can be misleading as it does not necessarily give a measure of the level or evenness of hydration of the endosperm.

The "chit" counts measure the consistency of a sample of steeped grain for a visible protrusion (the chit) of the developing rootlet/cotyledon from the base of the grain (Figure 4). A high value indicates that the grain batch is initiating germination consistently.

Germination

Steeped barley grain is transferred to germination vessels as either slurry or by dry transfer after draining.

The germination process aims to encourage enzyme synthesis and release, cell-wall breakdown in the endosperm, and the solubilization of stored nitrogen (proteolysis).

In the past, germination was carried out by spreading the steeped grain on the floor (Figure 5). Some

manual floor maltings still exist today and may be particularly suited to producing specialized malts such as those used for the production of single malt whiskeys. In floor maltings, the bed of grain was turned over manually to allow fresh air to circulate and prevent overheating from grain respiration. Nowadays germination is carried out using a pneumatic system in vessels of various shapes and sizes (generally from 40 to 400T) such as drums (Figure 6) or more typically rectangular Saladin boxes (Figure 7), or round germination vessels. In the pneumatic system, humidified temperature-controlled air is circulated through the grain bed (generally 1 m deep). The grain rests on perforated plates (Figure 8) and is turned automatically by rakes, which travel slowly through the grain bed (Figure 9). Temperature, airflow, and small applications of water are used to maintain moisture, temperature, and oxygen levels in the respiring grain mass as it germinates and grows. Turning the bed of grain keeps the grain mass loose and allows adequate airflow and water distribution.

During the germination stage, grain moisture increases to ~45% and roots and shoots begin to grow. Germination is typically allowed to proceed for 3–5 days during which time enzymes are produced from the scutellum and aleurone, and regulated in response to stimulation from hormones such as gibberellic acid (GA), indoleacetic acid (IAA), and abscisic acid (ABA). Enzymes produced or activated during this stage include α-amylase, β-amylase, limit dextrinase, α-glucosidase, β-glucanase, xylanase, and

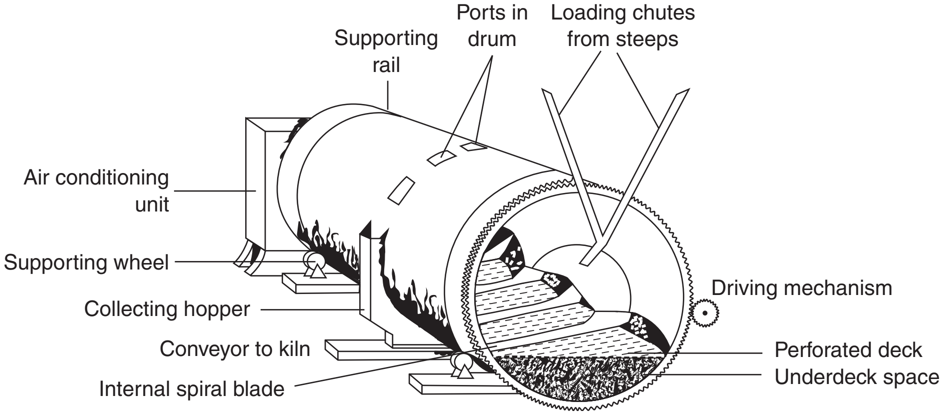

Figure 6 Cross-section of a drum used for germination using the pneumatic system.

Figure 9 Grains resting on perforated plates automatically turned by rakes.

endo- and exoproteinases. Activated enzymes are produced in sequence and move through the hydrated endosperm degrading both cell walls and protein matrix in which starch granules are embedded. This process is often referred to as grain modification.

At the end of the germination process, the cells walls of the starchy endosperm should be evenly and fully degraded with little or no starch granule degradation (Figure 10). Approximately 40–50% of the proteins should have been solubilized and high levels of starch degrading enzymes, in particular α- and β-amylase, should have been released. The grain moisture should have peaked at ~45% on day 2 and reduced to 38–40% at day 4. Once the grain has germinated it is referred to as "green malt."

Kilning

Transferring the green malt to the kiln halts the process of germination. Green malt is loaded to the kiln at ~40% moisture and is dried to 4–5% usually over a 24 h period. Kilning aims to prevent further root and shoot growth, to limit starch modification, to achieve a stable product for storage and transport, to preserve enzymes, and develop and stabilize color, aroma, and flavor. The process also removes undesirable flavors and chemical compounds. Once kilned, the malt is friable and can be milled for brewing or stored whole in cool dry conditions for up to 12 months without significant loss of quality.

The kilning process is the regulated removal of water from germinated grain. Moisture is removed from the grain by passing heated air through the grain bed. The air flowing to the kiln is gradually increased in temperature such that the grain

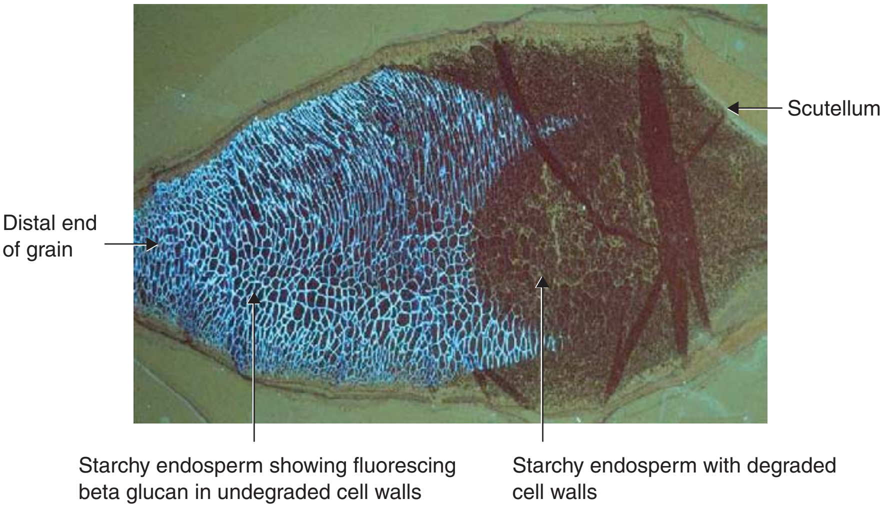

Figure 10 The cells walls of the starchy endosperm are degraded during germination.

temperature increases slowly and moisture within the grain diffuses to the surface of the kernel where it is absorbed and removed by the hot air stream. Since the grains form part of a grain, bed heating must be carefully controlled to allow moisture to be removed from the center of the grains in each of the layers in the grain bed without overheating the grains closest to the heat source.

There are typically three phases of moisture removal during kilning. In the "free drying" phase, moisture moves out of the grain relatively quickly, grain moisture drops rapidly and evenly to ~25%, and kiln temperatures are relatively low (50–60°C). This stage is followed by the "intermediate" phase where removal of moisture from the grain without overheating is more difficult. In this phase, temperature is increased slowly in a stepwise fashion over several hours and moisture drops to 12%. In the third and final "bound water" or "curing phase," moisture falls to ~4% as air temperatures are increased to 80+°C. Careful regulation of temperature, moisture removal, and time is essential to ensure that as the grain is dried, the hydrolytic enzymes that will be required in the brewing or distilling processes are not denatured, color is controlled, and the formation of unacceptable chemical compounds such as nitrosodimethylamine (NDMA) and dimethyl sulfide (DMS) are inhibited or minimized.

Kilning conditions are one of the largest contributors to the final malt character and it is careful control of this stage that allows a range of speciality malt types to be produced from the malting process (Table 1). Malts with colors from 2 to 30°EBC can be produced in a normal malt kiln without the need for roasting. Roasted products are higher in color at 35–1500°EBC and may be produced from barley, malt, or green malt (Table 1). These products are kilned in a specialized drum roasting plant at very high temperatures, which destroy all enzymic activity, but produce very characteristic and strong flavors and colors (Table 2).

Conventional kilns can be constructed in various shapes and sizes and may be single or double decked. In some situations, both germination and kilning can be carried out in the same vessel usually referred to as a GK vessel. Historically, kilns were constructed in brick, however, today kilns are typically constructed from metal or concrete with a bed depth up to 1 m (Figure 11).

In order to minimize NDMA formation, which is undesirable due to its potential carcinogenic properties, kiln gases are low in nitrous oxide and/or heat is applied indirectly using heat exchangers to avoid direct contact of the kiln gases with the malt.

The hot air is forced through the grain bed, which rests on a perforated floor similar to that found in the germination beds.

Hot air exiting the grain bed can be recirculated and this process is used to control the drying process and conserve energy consumption. Regulation of the relative humidity of the air removed from the grain can be used to protect malt quality. During kilning, embryo viability is destroyed, sucrose levels increase, and sugar is caramelized. Melanoidins increase via complex nonenzymic reactions and low-molecular-weight flavor substances such as acids, alcohols, aldehydes,

ketones, and esters are formed leading to the development of characteristic malt flavors and aromas.

Product Storage and Evaluation of Malt Quality

Following kilning, malt is cleaned to remove rootlets and small and ungerminated grain. Cleaning and rootlet removal is generally carried out prior to storage as rootlets can add a bitter taste to malt and add considerable bulk to the material to be stored. Malt offal is a useful stock feed.

The malted barley is now friable and easily broken and damaged. Damaged malt generates dust, reduces the husk component required for lautering in brewing, and increases production losses. Malt movement should be minimized and conveying speeds optimized to reduce such damage.

Individual batches of malt are assessed during processing and on completion of kilning for key quality characteristics using standard methods of analysis (IGB, ASBC, or EBC) and according to the malt specifications negotiated with the customer.

The use of rapid in-process tests for green malt moisture, color, β-glucan, and soluble nitrogen allow process to be optimized to achieve the target malt specification.

Malt House Design

Malt house design is varied and dependent on the site characteristics and production requirements. The decision to construct separate steeping, germination, and kilning vessels through various combinations to a full tower mating where the vessels are stacked on top of each other (Figure 12) is determined to a large extent by the range of products and customers to be serviced and the costs of construction in different locations.

In all cases modern plant design utilizes materials and layout that will take account of hygiene and energy efficiency.

Hygiene

Malt is an ingredient in the food chain. It is important that the barley selected for the process is free from chemical residues and foreign material and that the malt processing vessels and environment are kept clean. The use of stainless steel vessels and streamlined plant design minimizes cleaning requirements and ensures a safe food quality production environment.

Energy Efficiency

Malting is an energy intensive operation. Key utilities, gas, electricity, and water account for ~10% of direct input costs. The major gas use is in kilning while electricity is used in driving fans, cooling, heating, conveying, and pumping. The knowledge and ability to monitor and continuously control temperatures and speeds in various areas of the malt house allows energy use to be optimized. Plant design can assist in minimizing the conveying, heating, and cooling requirements and therefore reduce utility usage and

Figure 11 Circular kiln.

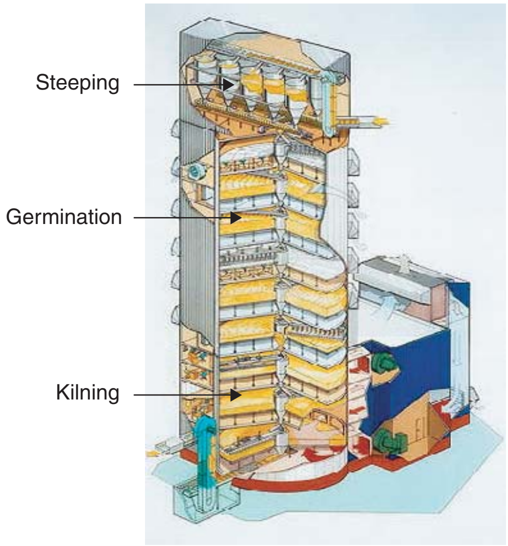

Figure 12 Tower maltings.

waste generation. In the future, the use of alternative energy sources: recycling and cogeneration plants will drive further energy savings and environmental sustainability in malting plants.

BEANS

S K Sathe and M Venkatachalam, Florida State University, Tallahassee, FL, USA

Introduction

Throughout human history, more than 3000 species of plants have been used as foods. On a global basis plants provide 65% of food protein, over 80% of food energy, and account for 85% of gross tonnage. Excluding the large number of fruit and vegetable species, only ~50 crop species make a significant contribution to human diet. Of these, cereals are the largest group followed by legumes in terms of global production. However, because legumes contain almost 2–3 times more protein than cereals, their dietary importance as protein source is well appreciated. Of more than 1300 species of legumes, only ~20 are most commonly consumed by humans. Among these, the common dry bean, *Phaseolus vulgaris*, is consumed in the largest quantity on a worldwide basis. Dry beans are low in fat (excluding oilseeds), low in sodium, and contain no cholesterol. They are a rich source of proteins, complex carbohydrates, fiber,

vitamins, and certain minerals. On a caloric basis, dry beans are more nutrient dense than cereals. Dry beans are less expensive than animal food products and when stored properly, have considerably longer shelf life than several animal, fruit, and vegetable products. Since legumes have the ability to fix atmospheric nitrogen and therefore add nitrogen to the crop–soil ecosystem, they are important in soil conservation and maintenance of soil quality.

Global Distribution, Varieties, and Commercial Importance

The word "legume" is derived from the Latin word "legumen" which means seeds harvested in pods. The term "pulse" (from Latin word "puls" meaning pottage) is used for legume seeds that contain small amounts of fat, while for those containing large amounts of fat (such as soybeans and peanuts) the term "leguminous oilseed" is used. According to the Food and Agriculture Organization (FAO), the word "legume" is used for all leguminous plants. The most commonly used legumes as human food are listed in Table 1.

Although legumes have been cultivated for several thousand years, the chronology and origins of domestication of food legumes is almost impossible to reconstruct. Some legumes (lentils for example) have been dated back to 7000–6000 BC. Leguminosae (or Fabaceae) is the third largest family of flowering plants (after Compositae and Orchidaceae) in size and economic importance and is second only to the grasses (Gramineae). Current estimates indicate that Leguminosae has ~16 000–19 000 species in ~750 genera. The subclassification is somewhat controversial. Almost all of the domesticated legumes used as food are members of *Papilionoideae*. All of the common beans belong to the tribe Phaseolae.

In terms of global production, legumes (including oilseeds) rank fifth in annual world grain production. Dry beans account for ~23.39% of the total world legume (pulses) production (Table 2). On a worldwide basis, the common beans (*Phaseolus* spp.) are the number one crop among dry beans (excluding oilseeds) in both production and consumption and are therefore economically an important crop. In 2001, the global dry bean supply was 2.1 kg per capita per year. Asia produces the largest quantity (44.90% of total world production) of dry beans followed by Latin America and the Caribbean (29.3%), South America (19.02%), North and Central America (17.23%), and Africa (15.26%). In 2001, Brazil (15.15%), India (13.58%), China (11.15%), Myanmar (9.06%), Mexico (6.56%), and the USA (5.49%) accounted for 61.00% of the global dry bean production. Europe, Asia, Latin America and Caribbean, and North and Central America lead world imports of dry beans in terms of dollar value (Table 2). Japan, US, UK, Italy, Mexico, India, Brazil, and France, respectively, accounted for 8.68%, 7.79%, 6.29%, 6.12%, 5.81%, 5.63%, and 5.19% of the total dollar value (49.39%) of worldwide imports ($992 052 000) of dry beans. Asia and North and Central America lead the worldwide export of pulses and dry beans (Table 2). In 2001, the leading exporting countries of dry beans were Myanmar, China, US, Argentina, and Canada, respectively, accounting for 22.73%, 20.97%, 14.73%, 10.49%, and 9.29% of the total dollar value (78.21%) of worldwide dry bean exports.

Morphology of the Pods/Seeds

Regardless of the fat content, most legume seeds have similar structure. Mature legume seeds have three major components: the seedcoat, the cotyledons, and the embryo axis. In most dry seeds, they account for 8–20%, 80–90%, and 1–2% of the seed weight, respectively. The majority of the nutrients are present in cotyledons. Typical seed structure and various anatomical parts of legume seeds are shown in Figure 1. The outermost layer of the seed is the seedcoat or testa. The external seed structure includes the hilum, micropyle, and raphe. The hilum is a scar-like structure (usually oval shaped) near the middle edge where the seed breaks away from the stalk. The micropyle is the small opening in the seedcoat where originally the pollen tube enters the valve. The raphe is the ridge at the side of hilum opposite to the micropyle and represents the base of the stalk that fuses with the seedcoat upon seed maturation. In most legumes, the endosperm is short lived and shrinks to a thin layer surrounding the cotyledons (or embryo). On soaking the seeds, the endosperm is easily removed along with the seedcoat. The remainder (embryo) of the seed consists of shoot (which contains two cotyledons), and a short axis above and below the cotyledons and terminates in the shoot tip. The plumule or embryonic stem is well developed in the resting seed and lies between two cotyledons.

The outermost layer of seedcoat is the cuticle, which has papillae or papillae-like growth in some legumes (e.g., green gram), but in most legumes it is a smooth structure. The thickness of the seedcoat is quite variable depending upon the type of bean. Generally, seeds containing thick seedcoats tend to have high fat content. Both hilum and micropyle are important in water imbibition by testa. Palisade cells derived from the outer epidermis of the outer integument, which are next to the cuticle, are either

Table 1 Grain legume species commonly used for food purposes[a]

Botanical name	*Common name*
Arachis hypogaea	Groundnut, peanut, monkey nut, goober pea, nguba
Cajunus cajan	Pigeon pea, arhar, red gram, tur, *toovar* Angola pea, gandal, ambre vade, alverja
Ca. indicus	Pigeon pea, Congo pea, yellow dhal
Canavalia ensiformis	Jack bean, horsebean, gotani bean, haba de burro, chickasaw, lima
C. gladiata	Sword bean, maxima
Cicer arietinum	Chick-pea, bengal gram, chana, deshi chana, kabuli, chiche
Ci. minotinum	Chana, garbanzo
Cyamopsis tetragonoloba	Cluster bean, guar, aconite, cyamopse
Dolichos biflorus	Horse gram
D. lablab	Hyacinth bean, bonavist, field bean, caballeros, Indian butter bean, val bean, Egyptian kidney bean
Ervum vulgaris	Lentils, masur dhal
Faba vulgaris	Windsor bean
Glycine max	Soybean, soja
G. hispida	
G. soja	
Lablab niger	Lablab bean
La. purpureus	Kidney bean, hyacinth bean, Indian bean, lubia bean
Lathyrus sativus	Grasspea, kesari dhal, vetch, chickling vetch, chicaro
Lens esculenta	Lentils, masur dhal, red dhal, lentille, split pea, lentija
Le. culinaris	
Lupinus spp.	Lupins, tarwi, tarin, pearl lupin, wolf bean, tremoco
Macrotyloma uniflorum	Horse gram, Madras gram, Kallu, Kulthi bean
Mucuna pruriens	Velvet bean, cowage, Mauritius bean, stizolobia
Phaseolus aconitifolius	Moth bean
Ph. acutifolius	Tepary bean, pavi, Yorimuni, dinawa
Ph. angularis	Adzuki bean, *feijao*
Ph. aureus	Mung bean, green gram, golden gram, chiroko, chicka sano pea
Ph. calcaratus	Rice bean, frijol arroz
Ph. lunatus	Lima bean, sieva bean, Madagascar bean, sugar bean, Burmabean, towe bean, pole bean, caraota, panguita
Ph. mungo	Mung bean, mungo bean, urd dhal, black gram, *urad*, woolly pyrol, kambulu
Ph. radiatus	Mung bean, golden graham, green gram
Ph. vulgaris	Dry bean, haricot, common bean, kidney bean, navy bean, pinto or snap bean, feijao, opoca, *rajma*, French bean, chumbinho
Pisum sativum	Dry pea, green pea, garden pea, field pea
Pi. angularis	
Pi. arvense	
Psophocarpus tetragonolobus	Winged bean (humid tropics), goa bean, asparagus bean, Colombo, four angled bean, princess bean
Sphenostylis stenocarpa	Yam bean
Stizolobium spp.	Velvet bean
Tetragonolobus purpureus	Winged bean (Europe)
Trigonella foenumgraecum	Methi, fenugreek
Tylosema esculentum	Marama bean
Vicia faba	Broad bean, horsebean, faba bean, field bean, Windsor bean
Vic. sativa	Vetch
Vigna aconitifolia	Moth bean, matki, mouth bean, mat, math
Vig. aureus	Mung bean
Vig. radiata	
Vig. mungo	Black gram, *urd, urad*, kambulu, pyrol
Vig. sinensis	Dry cowpea
Vig. umbellata	Rice bean, red bean, mambi bean
Vig. unguiculata	Black-eyed cowpea, black-eye pea, cowpea, kaffir bean, Hindu pea, asparagus pea
Voandzeia subterranea	Bambara groundnut, Madagascar groundnut, earthpea, Congo goober, kaffir pea, jugo bean, haricot pistache

P = Pulses and D = Dry beans.

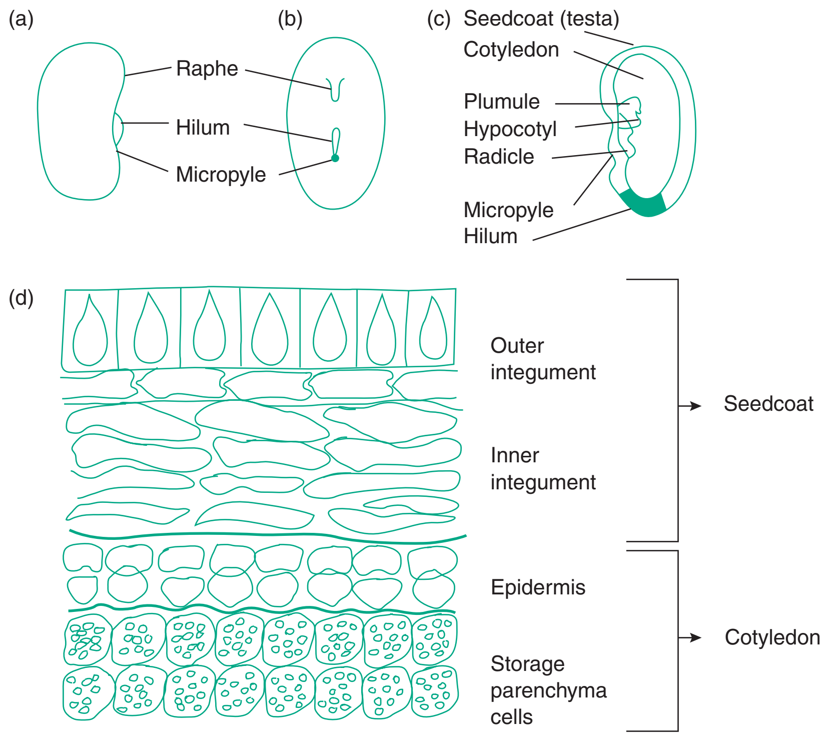

Figure 1 Dry bean (*Phaseolus vulgaris*) seed: (a) external side view, (b) external face or edge view (viewing at hilum side), (c) cross-section (one cotyledon removed), and (d) detailed cross-section across seedcoat and cotyledon. (Reproduced from Encylopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 407, Elsevier Ltd.)

loosely packed or densely packed, depending upon the seed maturity and may affect seed hydration. Next to palisade cells are the hourglass cells. The shape of hourglass cells can vary from bottle shape (guar) to dumbbell shape (broad beans) to hourglass shaped (soybeans). Only a few legume species (such as *Dolichos*, *Cajanus*, and *Vigna*) have more than one layer of hourglass cells. The remainder of the testa contains primarily mesophyll cells.

Legume cotyledons are primarily composed of parenchyma cells, which have variable size (70–100 μM) and act as storage sites for most nutrients. Each cell of the cotyledon is bound by the cell wall and the middle lamella. Vascular bundles in cotyledons generally are devoid of any filling material. Vascular bundles are often used as key structures in the identification of different plant types.

Chemical and Nutritional Composition

The majority of nutrients in dry beans are primarily located in the cotyledons and account for up to 90% of the total nutritive value. Typically, dry beans provide 1255–1464 kilojoules (kJ) per 100 g of dry seeds. The majority of constituents of cotyledons are proteins and carbohydrates and respectively account for 15–25% and 50–75% of the total seed weight. The remainder consists of fat, minerals, fiber, and vitamins. With the exception of oilseeds, dry beans generally contain low amounts (1–3% of seed weight) of fat. Although most minerals are present in cotyledons, some (such as calcium and iron) may be present in seedcoat in significant proportion. Typical nutrient composition of several *Phaseolus* beans is shown in Table 3. Dry beans not only contain significant amounts of nutrients, but also several undesirable components and attributes: inhibitors of enzymes such as trypsin, chymotrypsin, subtilisin, amylases, and elastase; lectins; phenolic compounds including tannins; phytates; toxic amino acids mimosine and djenkolic acid; cyanogenic glycosides which produce HCN; flatulence causing oligosaccharides raffinose, stachyose, and verbascose; lipoxygenases, which catalyze the development of rancidity; and off odors often described as beany, grassy, painty, cardboard-like, and chalky.

Proteins

Phaseolus beans are not only important for their caloric contribution to human diet but are especially valued for their protein content since they are a major protein contributor to the human diet on a global basis. In certain parts of the world they are the sole source of dietary protein. Dry bean proteins can be classified as storage and metabolic proteins. The original protein classification proposed by Osborne was based on solubility of proteins in a series of solvents. In this scheme the water and dilute salt soluble proteins were termed as albumins and globulins, respectively. Dry beans contain 40–60% globulins and 20–40% albumins based on Osborne's protein classification. Globulins are exclusively storage proteins while albumin fraction contains both storage and metabolic proteins. The protein content of dry beans is usually calculated by multiplying Kjeldahl nitrogen content by a factor of 6.25. Because dry beans contain 10–15% of total nitrogen as non-protein nitrogen, most dry bean protein values are typically overestimated by 1–2%.

[a] Data compiled from Sathe SK, Deshpande SS, and Salunkhe DK (1984) Dry beans of *Phaseolus*: a review. Part 1. Chemical composition: proteins. *CRC Crit. Rev. Sci. Nutri.* 20: 1–46 and Salunkhe DK and Kadam SS (1989) *Handbook of World Food Legumes: Nutritional Chemistry, Processing Technology, and Utilization*, vols. I (310pp.), II (294pp.), and III (323pp.). Boca Raton, FL: CRC Press. Data expressed on dry weight basis.

The major storage proteins in dry beans have been identified by several names and therefore their nomenclature is somewhat confusing. Based on the nomenclature using ultracentrifugation sedimentation coefficient (*S*), dry beans contain both 7*S* (vicilin-like) and 11*S* (legumin-like) storage proteins. Depending on the bean variety, the relative proportion of these two types of proteins varies considerably. The 11*S*-type proteins typically are nonglycosylated proteins with estimated molecular weight (MW) in the range 300 000–400 000. They are usually composed of six subunits (MW 60 000), each consisting one acidic (MW 40 000) and one basic (MW 20 000) polypeptide linked by disulfide bond(s). Usually, 11*S* proteins are present in minor amounts in *Phaseolus* beans. The 7*S* globulin in *Phaseolus* beans has also been referred to as glycoprotein II, globulin 1, euphaseolin, globulin, and phaseolin. Depending on the type of bean, the 7S globulin type and quantity varies considerably. In *Phaseolus* beans the 7S globulins are, however, the major storage proteins and account for 40–60% of the total proteins. The three major types of 7S proteins that have been identified, biochemically purified, and characterized are: (1) Phaseolin, (2) Lectin (also called glycoprotein II, phytoagglutinins or phytohemagglutinins, and protein II), and (3) Arcelin in wild bean accessions from Mexico (named after town Arcelia in Mexico, where some of the accessions were collected). All the 7*S* globulins are glycosylated and contain D-mannose and D-glucosamine as the major sugar constituents.

Phaseolin Phaseolin is the major globulin in domesticated *Phaseolus* beans. It is a trimeric, vicilin-like 7*S* globulin known to exhibit polymorphism. The polypeptide polymorphism is believed to be due to not only the differential glycosylation but also because phaseolin polypeptides are encoded by a small multigene family. Phaseolin is soluble in 0.5 M NaCl at all pH values. It undergoes reversible pH-dependent dissociation–association with sedimentation coefficients of 3.0*S* (pH 12.0), 7.1*S* (pH 7.0), and 18.2*S* (pH 3.6) known as peptides (MW 44 000), protomers (MW 163 000), and tetramers of protomers (MW 653 000). Phaseolin consists of a group of subunit polypeptides with MWs 43 000–54 000 and isoelectric points from pH 5.6 to 5.8, depending on phaseolin type. Among *Phaseolus* beans, three distinct types of phaseolins – named after cultivars Tendergreen (T), Sanilac (S), and Contender (C) – have been identified. Screening of 107 cultivars has revealed that S-, T-, and C-type phaseolins accounted for 69%, 25%, and 6%, respectively, of the total cultivars. These types can be easily distinguished by one-dimensional or two-dimensional gel electrophoresis using sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (PAGE) for one-dimensional or isoelectric focusing in first dimension followed by SDS-PAGE in the second dimension for two-dimensional gel electrophoresis. The C-type phaseolin is believed to have originated from T and S types. Regardless of the type of phaseolin, phaseolin contains 3–5% carbohydrates and its amino acid composition is dominated by acidic amino acids (30–40% of total). Typically, the N-glycosylation sites in phaseolin polypeptides occur at amino acid residue numbers 252 and 341. Sulfur-containing amino acids (notably methionine) are the limiting amino acids in phaseolin as well as other major storage proteins in *Phaseolus* beans. The secondary structure of phaseolin in 0.5 M NaCl typically has a low α-helix content (10%) and β-turns (9.0%) and large amount of β-sheet (48.0%) and random coils (33.0%). Native phaseolin is quite resistant to digestive proteases such as pepsin, trypsin, and chymotrypsin and is degraded to polypeptides with MWs 24 000–28 000. However, heat denatured phaseolin is easily digested by these proteases.

Lectin Bean lectins agglutinate erythrocytes due their ability to bind with cell surface glycoproteins and glycolipids. Although the precise function of lectins in beans is not known, they are thought to offer protection to the plant. Since lectins are toxic, they are of nutritional concern. Lectins occur in both albumin and globulin fractions. Certain bean cultivars lack lectins. When present, lectins represent 6–12% of total protein. In addition to agglutinating activity, many bean lectins have mitogenic activity. Most lectins of *Phaseolus* beans have subunits of MWs 29 000–36 500 with isoelectric pH in the range 4.9–7.9 (most are in the pH range 5–6). The majority of the native lectins have tetrameric nature (MWs 100 000–150 000) although some (lima beans for example) have dimeric nature. The majority of *Phaseolus* lectins have 4–6% carbohydrate, low sulfur-containing amino acids, and sugar specificity towards D-acetylgalactosamine. Lectins are very resistant to common digestive proteases and are slowly hydrolyzed *in vitro* even after extensive heat denaturation. Proper moist heat denaturation can completely inactivate the biological activity of lectins and therefore can render them nontoxic.

Arcelin Arcelin was first discovered in wild accessions of Mexican *Phaseolus* beans. It also occurs in lines that contain phaseolin as well as lectin. Because it is present in equal or greater levels than phaseolin in certain lines, it is one of the major storage proteins in *Phaseolus* beans. The MWs of arcelin subunit polypeptides range from 35 000 to 42 000 depending on

the variant, and are more basic than both lectin and phaseolin. The native arcelin has an MW of 89 000 and is therefore a dimeric protein. Arcelin has many similarities with lectin (including agglutinating activity) with respect to chemical composition.

Other proteins *Phaseolus* beans contain trypsin inhibitors (many of them also inhibit chymotrypsin), amylase inhibitors, lipoxygenases, and several other minor protein components. Most of these proteins are a part of albumins. Trypsin and chymotrypsin inhibitors in *Phaseolus* beans typically account for up to 10% of the total proteins and are generally rich in sulfur amino acids. The MWs of these inhibitors range from 2000 to 23 000. Most Phaseolus beans lack Kunitz-type (inhibitors with 170–200 amino acids with MW of ~20 000) trypsin inhibitors. Amylase inhibitors in dry beans have been characterized from only a few cultivars and therefore not yet extensively studied. The MW of kidney bean amylase inhibitor (a glycoprotein) has been shown to be 50 000. Appropriate moist heat treatment (such as cooking or autoclaving) can inactivate both the protease and amylase inhibitors.

Allergenic Proteins

With heightened concerns about food allergies and the increased frequency of food recalls due to actual or suspected presence of allergen in food, food-induced allergens are of increased interest to consumers and regulatory agencies alike. Since any food protein could be a potential allergen, it is important to recognize that dry bean proteins may be allergenic. Compared to aeroallergens, such as pollen, perhaps with the exception of peanut proteins, very little is known about seed protein allergens in general and dry bean proteins in particular. A few dry bean proteins have been identified to be allergens (Table 4) and even fewer have been characterized at molecular level. Phaseolin, the major storage globulin in dry beans, has not yet been reported to be an allergen. Among the legume proteins identified to be allergens, majority appear to be storage proteins such as 2*S* albumins (e.g., Ric c 1, Ric c 3, soybean MRP), 7*S* or vicilin-like proteins (e.g., Ara h 1, β-conglycinin, Len c 1), and 11*S* or legumin-like proteins (e.g., soybean glycinin, Ara h 3, Ara h 4), some of which are glycosylated (Ara h 1, Gly m Bd 28 k) while others are not (soybean glycinin). Since typical thermal food processing does not significantly hydrolyze food proteins, linear stretches of amino acids responsible for IgE binding, the linear epitopes, are expected to survive normal food processing operations. For these reasons, food processing is often unable to completely inactivate food allergens. It is therefore also not surprising that some investigators find many legume allergens to be acid and heat resistant.

Carbohydrates

Total carbohydrates in *Phaseolus* beans contribute 50–70% of the seed weight and include mono-, di-, and oligosaccharides; starch; and other polysaccharides. Starch is the most abundant nutrient in *Phaseolus* beans accounting for up to 70–80% of total carbohydrates. Among the simple sugars, oligosaccharides (raffinose, stachyose, verbascose, and ajugose) are the major constituents (up to 10% of seed weight) and are at least partially responsible for flatulence production. Crude fiber is primarily composed of cellulose, hemicellulose, lignins (not a carbohydrate), and other nonstarchy polysaccharides such as arabinogalactans, arabinoxylans, glucomannans, galactomannans, and pectins. The hypocholestermic effect of dry beans is partially attributed to the presence of nonstarchy polysaccharides. *Phaseolus* bean starch granules are quite variable in shape (round, oval, oblong, elliptical, spherical, kidney shape, and irregular) and size (5–60 μm) and typically contain 10–45% (of total starch) amylose. The average degree of polymerization for amyloses and chain lengths for amylopectins of *Phaseolus* bean starches range from 1600 to 1900 and 22 to 26, respectively. Based on X-ray diffraction spectra, *Phaseolus* dry bean starches are mostly C type (mixture of A (typical of cereal starches) and B (typical of root and tuber and high-amylose cereal starches) types). These starches have restricted swelling, gelatinization temperature range of 60–89°C, high solution viscosities, and good thermal stabilities. Upon gelatinization they produce opaque gels. Dry bean starches (especially if cooked) are well digested (digestibility is comparable to those of many cereal and tuber starches) by humans. Because dry bean starches are digested slowly, however, they are hypoglycemic and therefore useful in the diets of diabetics.

Vitamins and Minerals

Phaseolus beans are a good source of B-vitamins, especially thiamin, riboflavin, niacin, and folacin. Typically, thiamine, riboflavin, niacin, and folacin contents (on a dry weight basis) of *Phaseolus* beans are, respectively, 0.5–1.14, 0.1–0.25, 0.4–3.14, and 0.037–0.676 mg per 100 g. Vitamin E content ranges from 0.72 to 1.97 mg per 100 g and B_6 content ranges from 0.2 to 0.659 mg per 100 g. *Phaseolus* beans are not good sources of vitamin A and C.

Phaseolus beans are excellent sources of several minerals including Ca, Fe, Cu, Zn, P, K, and Mg.

Typically, raw beans contain 70–260, 0.5–1.40, 3.34–13.5, 160–320, 1.0–2.1, 380–570, 1320–1780, 4.0–21.0, and 1.9–6.5 (all expressed as mg per 100 g, dry weight basis) of Ca, Cu, Fe, Mg, Mn, P, K, Na, and Zn, respectively. Low sodium and high potassium content of raw beans makes them a desirable constituent of human food (especially for people with hypertension).

Antinutritional Factors

In addition to protease inhibitors and amylase inhibitors, *Phaseolus* beans contain several other antinutritional and antiphysiologic factors such as phytic acid, tannins, cyanogenic glycosides, saponins, and allergens. Because these components are usually present in small quantities (less than 5% of the total seed weight), they do not pose a serious health hazard under normal conditions (that is when beans are a part of total diet and are properly processed prior to consumption). Of these antinutritional factors, phytates and tannins are of particular concern because both of them are heat stable and cannot be easily removed from beans during normal home processing. Phytate is a general term used for mono- to dodeca anions of phytate along with esters lower than hexaphosphate. Ca–Mg salts of phytic acid (myoinositol 1, 2, 3, 4, 5, 6-hexakis (dihydrogen phosphate)) are referred to as phytin. In most dry beans phytate phosphorus accounts for up to 80% of the total phosphorus. The amount of phytate in *Phaseolus* beans range from 0.6% to 2.1% (by weight) of the total seed weight. Because phytates are chelating agents, they may interfere in mineral utilization. Germination, fermentation, and soaking followed by cooking (if both soak- and cook-water are discarded) are effective methods of removing phytates (50–80% reduction).

Tannins (especially condensed tannins) are heat-stable compounds and are present in *Phaseolus* seeds (especially in colored varieties) up to 2% of total seed weight. Because of their ionic character, they may interact with other constituents (notably proteins) and adversely affect the nutritional bioavailability of that constituent. Tannins are thought to offer protection to the plant from insects and pests.

Lipids

Phaseolus beans contain 1–3% lipids (by weight) depending upon the species. Neutral lipids (30–50% of total) and phospholipids (25–35% of total) are the major constituents and glycolipids may account for up to 10% of the total lipids. Regardless of the variety, *Phaseolus* bean lipids primarily contain palmitic, oleic, linoleic, and linolenic acids. Polyunsaturated fatty acids and saturated fatty acids typically account for 55–87% and 12–28% of total lipids.

Beneficial Bioactive Compounds

Continuing research on raffinose oligosaccharides, phytates, tannins, simple phenolic compounds, sterols, protease inhibitors, and several other major and minor constituents of dry beans suggests that some of these compounds, under appropriate conditions, may offer beneficial effects for human health. Long-term detailed and fundamental research is needed to fully realize the potential health benefits of dry bean consumption.

Grading, Handling, and Storage

Dry beans are usually harvested at maturity. The seeds are removed from the pods either manually or mechanically and cleaned to remove dirt, stalks, leaves, blemished, and wrinkled seeds, and packaged prior to storage. The grading of seeds is usually based on external characteristics such as color, gloss, seed size, seed soundness, seed firmness, and presence of contaminating substances. The seeds are stored at farmer, trader, or government levels. Typically, farmers hold up to 8% of harvested seeds until next season so that they can be used as planting seeds if crop failures occur. In developed and developing nations, a majority of the seeds are stored by traders and/or governments to protect against subsequent crop failures (or low yields), price fluctuations, and fluctuations in supply (change in demand, shortages, and famines). Losses in seeds occur both pre- and postharvest. The normal preharvest losses are mainly due to birds and mammals feeding on bean plant seeds. Drought/floods, insects, and rodents can also contribute to preharvest losses. In developed nations, preharvest losses are usually small (as low as 1% of the crop). A majority of the losses occurs during postharvest handling and storage and can range from 8% to as high as 50% of total crop. It is estimated that as much as 48% of food produced in the world is lost (due to pre- and postharvest losses). Factors that influence postharvest losses of legumes include moisture, temperature, respiration rate, insect damage, microbial spoilage, and damage caused by mites and rodents. Properly packaged dry beans should be stored at low relative humidity and temperature conditions. High relative humidity and temperature favor the "hard-to-cook" beans. These conditions also favor the growth of molds and insects. Three major insect genera that cause much of the damage to stored legumes are *Bruchus, Acanthoscelides*, and *Callosobruchus*. De-husked, split stored pulses are

also damaged by *Rhizopertha, Trogoderma*, and *Tribolium* species. Usually, pests seem to have preference for the type of bean they infest although the basis for such preference (or the lack of it) has not been elucidated yet. The major microbial problem during bean storage is contamination by aflatoxin-producing molds (*Aspergillus flavus* and *Aspergillus parasiticus*). Mites can consume food up to their own weight (6–8 μg) and because of their large numbers can cause serious losses. Rodents cause twofold damage to stored legumes by not only consuming but also contaminating (up to 20 times the amount they would eat). Because rodents are carriers of many communicable diseases, they pose serious damage to stored beans. The species that most commonly cause damage include *Rattus rattus*, *R. norvegicus*, *Bandicota indica*, *B. bengalensis*, and *Mus muscalatus*.

Processing and Food Uses

Phaseolus beans are processed and used in a variety of ways. The processing of beans is mostly at the household level in developing and underdeveloped countries, while in most developed countries the majority of the processing is done at the industrial level. Home processing methods include milling, soaking, cooking, frying, germination, fermentation (either alone or in combination with cereals), roasting, puffing, parching, extrusion and frying, and toasting. The method(s) used for home processing depend on regional preference for bean variety and the desired end product. For example, mung beans in sprouted form are popular on global scale and therefore germination is one of the preferred household processing methods used. Black gram, on the other hand, is extensively used for preparation of "idli," a breakfast food popular in India and Sri Lanka, after fermenting it with rice. Industrial processing includes freezing for such beans as green French beans, snap beans, etc., milling (production of flours and high-protein flours), baking (baked beans), cooking and frying (refried beans), and canning (alone in salt water or tomato juice or in combination with meats such as beef and pork). In developing countries, de-husking and splitting to produce "dhal" is also done at industrial scale.

In developing and underdeveloped countries *Phaseolus* beans are used in numerous ways depending on the type of bean and regional preference. They may be eaten as raw, immature seeds; cooked as green vegetables (such as French beans); consumed as part of salads; used in making curry; used as a soup ingredient; cooked, mashed, mixed with condiments and spices and used as gruels and porridges; prepared as pastes to be extruded to prepare fried snack products; sprouted; puffed or roasted and eaten as snack foods; and fermented to prepare numerous fermented products.

In developed countries *Phaseolus* beans are consumed as salad and soup ingredient, sprouts, canned, frozen, and refried beans. They are also extensively used in the preparation of Mexican style preparations, such as burrito, chimichanga, taco, bean dips, tamale, etc., and often canned with meats such as beef and pork. In many South American countries cooked black beans are a preferred part of breakfast.

Although there is a good potential for the preparation of protein concentrates and isolates and the development of food starches, *Phaseolus* beans have not been used on large scale for such purposes. In many countries, especially the developed ones, *Phaseolus* beans have been extensively used as animal feed. In developing and underdeveloped countries, the green foliage, deseeded pods, and roots and shoots of bean plants are used as natural fertilizers especially after composting. Because the legume roots fix nitrogen, they help conserve soil quality. For this reason, in many developing countries they are extensively used for soil quality conservation.

Asian Alcoholic Beverages

D K O'Toole, City University of Hong Kong, Hong Kong, People's Republic of China

For many centuries, China and other East Asian nations have used a mold-based system for the production of alcohol from grains. This mold-based system has also been adapted to the production of other fermented products such as soy sauce. The foundation of the system is "koji" (Japan), or "jiuqu" (China). Grain is prepared and mold allowed to grow on it. The mold enzymes include α-amylase, gluco-amylase, as well as proteases. To produce rice wines such as "saké" and Chinese rice wines, the molded grains are mixed with rice, and in a complex process the rice is converted to an alcoholic beverage. The distilled sorghum liquors depend on a semisolid fermentation followed by steam distillation. This is done up to 8 times with the same batch of sorghum with "daqu" being added after each distillation.

Introduction

Yeasts can only produce alcohol from soluble monosaccharides and disaccharides, most commonly from glucose and maltose. Two sources of these sugars are fruit juices and starch, but the starch is insoluble and the sugars are in polymeric form and so generally unavailable to yeasts. In the West, this unavailability problem was solved by using sprouted barley to release enzymes that breakdown the insoluble starch in the grain to sugars for yeast growth. However, in China, after an attempt ~3000 years ago to use sprouting grain to brew "Li" from "Nie" in a process similar to beer brewing, the idea was dropped in favor of a microbial-based system in which "Jiu" was brewed with "Qu" Modern beer making was only introduced to China in 1900 at Harbin by Russians. The ancient Chinese system depends on growing mold on grain, essentially a solid-state fermentation for enzyme production, mixing the molded grain with cooked grain and water, then soaking it in water to allow the enzymes from the mold to breakdown the starch, followed by a yeast fermentation to produce alcohol. Rice wine or Japanese saké are the modern descendents of this technological innovation.

The molded cereal-based system starts with wet grain, cooked or uncooked, so that molds grow on the grain to produce carbohydrate degrading enzymes. In Japan, this molded product is called koji, in China it is qu or jiuqu, in Korea it is "nuruk" (or "nuluk"). In Southeast Asian countries, a similar powdered-rice product is made and they go by the names "bubod," "ragi," "lakpaeng," "men," and "mochikouji," but rice is not necessarily the source of sugar. In the Philippines, the wet form of koji is called "binubudan" and sugar cane juice is fermented. Koji is used to produce a variety of foods, apart from alcoholic beverages, throughout east Asia. This microbial-based system of alcohol production has a long history, dating back to the Xia Dynasty, ~4000 years ago, but archeological artifacts associated with the technology have been dated to over 5000 years ago. Jiuqu has been specifically mentioned in Chinese literature dating from the Zhou Dynasty (770–221 BC). As with beer in the West, for centuries in China, and even now, some alcoholic beverages are thought beneficial to health.

In China, this mold-based system is used to make grain-based distilled liquors and wines, e.g., from rice, corn, millet, and sorghum. The Japanese have developed saké-brewing systems based on the scientific study of the organisms and processes while Chinese systems tend to be more traditional and far more complex.

Saké Brewing

The Japanese rice wine production began ~300 BC and today there are ~10 000 brands of saké produced in ~2000 factories. The Japanese have developed pure fungal and yeast culture based systems for rice wine production as opposed to the traditional rice wine making systems mostly used in China. Saké is classified according to the degree of polishing of the rice used to make the wine (Table 1). Rice grain weight reduction is from 25–35%. Generally, "ginjo saké" is made with highly polished rice while "honjozo saké" is made with rice not polished below 60%. Less highly polished rice results in a higher level of inosinic acid that is responsible for the characteristic flavor of saké.

Koji Production for Saké

Brewers favor large rice grains with soft kernels so that water uptake is rapid and mold mycelia can penetrate the kernels more easily (Figure 1). The mineral content of the water influences saké quality, iron levels must be low and potassium, phosphorus, and magnesium are required for mold growth, and calcium and chlorine improve fungal amylase extraction.

Table 1 Types of saké are based on the Seimaibuai classification that relies on the percentage of original rice left after the rice has been polished

Type of saké	*Seimaibuai classification (% of rice left after polishing)*	*Comment*
Junmai dai ginjo	50	Highest grade of saké, light dry type
Junmai ginjo	60	Sweeter, heavier than above
Tokubetsu junmai	60	"Special Junmai," a marketing product
Junmai	70	Means "pure saké," no added alcohol, with heavier, fuller flavor

The lesser the percentage of original rice, the lighter and more delicate is the flavor of the saké.

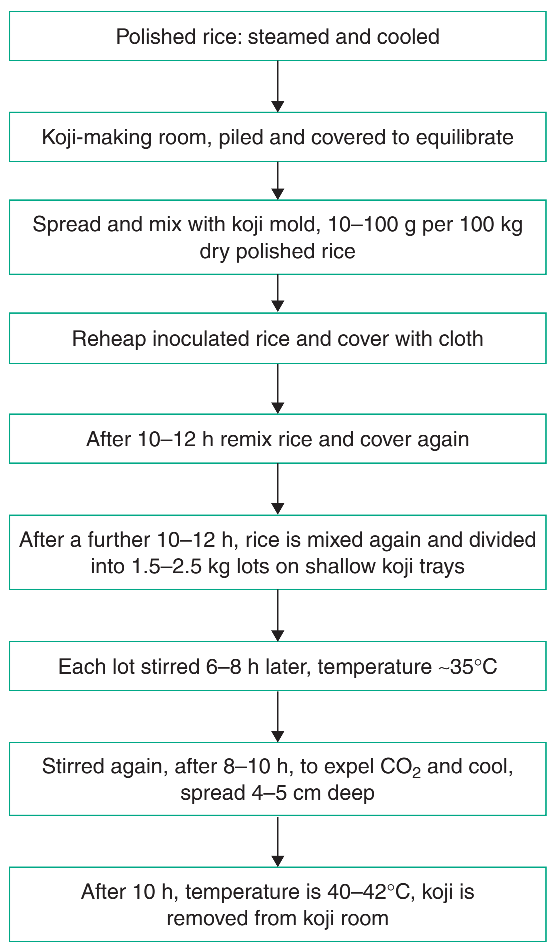

Figure 1 Koji production for saké manufacturing is an intensive process designed to maximize enzyme production.

The pH should be neutral to alkaline, of medium hardness (German scale 3–7) and highly chlorinated.

After washing off loose bran, the grains are steeped to take up water equal to 25–30% of the milled rice weight. The drained, steeped rice is then steamed in shallow open vessels for 30 min to 1 h, in batch systems, for a shorter period in continuous systems, so that the weight of the grains increase a further 8–12%. The rice is then cooled to 34–36°C and transferred into the koji-making room where temperature and relative humidity can be controlled, and piled on an insulated bed and covered with cloth to allow equilibration with the room. The grains are then spread evenly and inoculated with "tane-koji," a seed culture of *Aspergillus oryzae* that has been grown for up to 6 days to maximize sporulation. It is inoculated at 10–100 g per 100 kg of polished rice, reheaped and covered with a cloth. The temperature rises as the fungus grows so the inoculated rice must be manipulated and mixed to control temperature.

The way the mold mycelia grow through the resulting molded grain influences the quality of the saké produced. If mold growth is confined to the outer layers of the grains, excessive breakdown of grain protein reduces saké quality. The fungus produces ~50 kinds of enzymes including proteases and amylases. Of particular importance are α-amylase (amylo-1,4-dextrinase) and *S*-amylase (amyloglucosidase), the former breaks down the starch molecules to smaller fragments to decrease viscosity, the latter removes glucose units (*see* **Enzyme Activities**).

Moto Production

In effect, this is the beginning of the brewing process because ingredients are added to the "moto," after it has been made, to make the saké. In moto production, yeast is prepared by a complex process that is, however, simpler than traditional methods. Water (200 l), rice-koji (60 kg), and steamed rice (120 kg) are mixed and held at 13–14°C for 3–4 days with occasional stirring. The temperature drops to ~7–8°C. During this stage, the koji enzymes begin the breakdown of the starch in the rice, and some wild bacteria and yeasts begin growing in the mix. However, lactic acid bacteria (*Leuconostoc mesenteroides* var. *saké* and *Lactobacillus saké*) begin growing and lower the pH. These acid conditions, along with the high levels of sugars, eventually kill off these organisms. The temperature rises to 15°C and by ~15 days a pure culture of saké yeast, a strain of *Saccharomyces cerevisiae* but with some unique characteristics (Table 2), is added to give a population of $\sim10^5$–$10^6\,g^{-1}$ that rises to $\sim10^8\,g^{-1}$ as temperature also rises to 20–23°C. A variation on this system is to add lactic acid to the moto mix to bring the pH down to 3.6–3.8 to prevent the wild microbial activity but the saké yeast must be added soon after. The characteristics of the water phase at yeast inoculation are: specific gravity, 1.124–1.128; reducing sugar, 26–28%; amino acid as glycine, 0.5–0.8%; total acid as lactic acid, 0.3–0.4%. Traditionally, it took 25–30 days to produce suitable moto.

Table 2 Some cultural characteristics that distinguish saké yeast and *S. cerevisiae*

Characteristic	*Response*	
	Saké yeast	*Saccharomyces cerevisiae*
Growth in vitamin-free medium	+	
Growth in biotin-free medium	+	
Tolerance to ethanol (% concentration)	20–23	16–19
Habitat	Found only in saké brewing	Widely found in fruits and other environments

Rice Wine Production

The wine-making process is basically a batch-fed system, the fermentation process is begun and further raw materials are fed into the "moromi" as it progresses (Figure 2). (Moromi is a general term to describe a fermenting mash based on grains on which fungi have grown.) The moromi stage of the process involves putting moto, at 12–13°C, in a vessel 6–18 kl in size along with steamed cool rice, rice-koji and water (Table 3). By this stage, the water phase of moto has a specific gravity of 1.028–1.043, an ethanol content of 12–15%, amino acid content of 0.45–0.65% and total acid content of 0.9–1.0%. The saccharolytic enzymes from the koji release the glucose from the rice starch thus making it available for the yeast to ferment.

There are three additions of water, rice-koji, and steamed rice to the vessel containing the moto, and as each addition is made the temperature is lowered by adjusting the temperature of the steamed rice and water so that by the fourth day the temperature is 7–8°C. The lower temperature controls wild microbial growth. The moromi is then agitated twice daily and by 3–4 days, the water phase composition is: specific gravity, 1.051–1.058; ethanol, 3–4%; total acid as succinic acid, 0.06–0.07%.

The yeast concentration reaches about 2.5×10^8 per g and the fermentation becomes more vigorous and temperature rises to about 13–18°C in

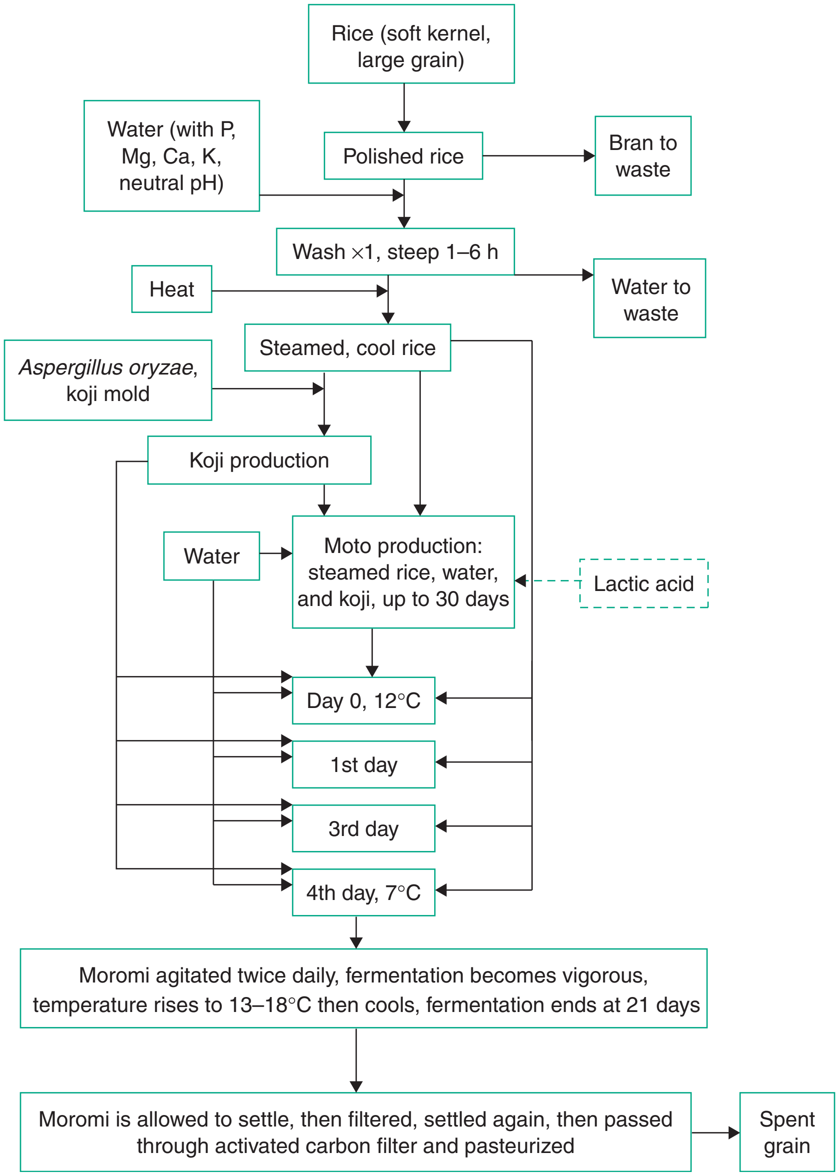

Figure 2 Saké production is a complex process involving the production of koji that is used to make a relatively small batch of starter material, the moto, to which is added further batches of steamed rice, koji, and water. Acid conditions to prevent growth of spoilage organisms are important; so in some cases lactic acid is added instead of relying on the natural growth of lactic acid bacteria in the moto. Temperature control is also important.

Table 3 The raw materials added progressively to the prepared moto to ferment the rice for saké

Preparation stage	*Day*	*Cumulative totals*			
		Total rice (kg)	*Steamed rice (kg)*	*Rice-koji (kg)*	*Water (l)*
Moto[a]	0	180	120	60	270
1st addition	1	510	360	150	500
2nd addition	3	1020	830	210	1230
3rd addition	4	1710	1350	360	2329
Total		3420	2640	780	4329

[a] Moto production takes 2–4 weeks to complete before the actual wine production begins.

6–9 days, where the temperature is held for a further 5–7 days until the ethanol content is 17.5–19.5% and the temperature begins to decline.

In the final stage, further additions may be made to the moromi. Pure distilled ethanol may be added to bring ethanol to 20–22%, 7–8% steamed rice allows production of excess glucose to sweeten the wine but pure glucose may be added, lactic acid and succinic acid may be added as well as glutamic acid. By 21 days, the density of the water phase is 1.004–1.000, reducing sugar is 3–2%, ethanol is 18.5–19.5% and the acid content as succinic acid is 0.14–0.16%.

The moromi is allowed to stand for a few days to settle and it is then filtered and again allowed to settle for 5–10 days. If the period is too long, the saké quality begins to deteriorate. It is then passed through an activated carbon filter, pasteurized, and stored at 13–18°C to mature before bottling.

Scientific Basis of Process

The wine-brewing process is conducted as a parallel fermentation, and is best conducted at low temperatures. Further, the development of low pH due to acid production by lactic acid bacteria or addition of lactic acid retards growth of spoilage organisms and permits the growth of yeasts. The parallel fermentation is unique in that while the enzymes are releasing the glucose from the starch, the yeasts are fermenting it to produce ethanol unlike beer where the soluble sugars are first released and then the fermentation is conducted.

From studies conducted in Japan, it is known that the release of the sugars initially from the steamed rice occurs rapidly. However, the increased glucose concentration suppresses α-amylase activity, so release of glucose declines until significant yeast activity reduces glucose and produces ethanol. The breakdown of the rice-koji in the moromi is more complex. The mold growth in the outer layers of the rice grain solubilizes the outer layer of starch rather quickly leaving variable amounts of a core of the rice grain that breaks down much more slowly under the action of the α-amylase. The breakdown of this inner core is dependent on the variety of rice used in the manufacturing.

Chinese Rice Wine Production

Unlike modern Japanese saké preparation methods, the Chinese traditional methods of preparation did not distinguish between the mold stage and the yeast stage, they were combined into one process that was very complex and varied enormously from place to place. However, pure cultures have been isolated and are increasingly being used but traditional methods are still used. In addition, constituents apart from rice may be used in the preparation so instead of steamed rice, barley, and millet are also used as the main source of starch.

Generally, Chinese rice wines are classified according to the residual sugar level, namely dry type, semidry type, semisweet type, sweet type, and extra-sweet type (Table 4). They are also classified according to the production method. The four basic methods and their names (Table 5) are:

Table 4 The Chinese classification of rice wines

Wine type	*Sugar (g per 100 ml, as glucose)*	*Ethanol (%, v/v)*	*Total acid (g per 100 ml, as succinic acid)*
Dry type	<0.5	>14.5	0.45
Semidry type	0.50–3.00	>16.0	0.45
Semisweet type	3.00–10.00	>15.0	0.55
Sweet type	>10.00	>13.0	0.55

1. "Ling fan jiu," e.g., "yuan hong" wine is a dry type wine. The hot steamed rice is cooled by drenching it with cold water then mixing the rice with jiuqu starter. It is commonly used as starter for inoculating more mash. It can be drunk after fermentation for several days.
2. "Tang fan jiu," e.g., "jia fan" wine that is a semidry type wine. The steamed rice is spread onto bamboo rafts to cool and then mixed with jiuqu, and acidified rice-steeping liquid.
3. "Wei fan jiu," e.g., "san niang" wine that is a semisweet type wine. This rice wine is produced using a fed batch fermentation method similar to saké production. The fermentation is begun as in the first process, but then steamed rice is added intermittently during the fermentation period, usually in three batches.
4. Fortified rice wine, e.g., "xiang xue" wine that is a sweet type wine. Aged rice wine or spirits distilled from refermented spent grains from rice wine are added before the main fermentation ceases. The final alcohol concentration is above 20%, consequently the microorganisms in the mash are inhibited, but the saccharification of the remaining dextrin to sugar in the main mash continues slowly, resulting in high residual sugar contents.

A general outline of the manufacturing process of Chinese rice wine is given in Figure 3.

Jiuqu Production

Chinese rice wine making begins with the preparation of a starter material called qu or jiuqu. The preparation is designed to encourage the growth of molds on prepared masses of grains and along with it yeasts also grow. The mold growth results in the production of enzymes in the jiuqu (*see* **Enzyme Activities**). The molded mass of grains is then shaped and dried for use as an inoculum in rice wine making. When the jiuqu is then added to prepared grains, such as steamed rice, the enzymes breakdown starch in the steamed rice just as malted grains can be used to breakdown adjuncts in beer production. However, unlike beer production, the jiuqu also fills the fermenting function, due to the presence of yeasts

Table 5 The ingredients and chemical composition of four kinds of Chinese rice wine

Component	*Types of rice wine*			
	Yuan hong	*Jia fan*	*San niang*	*Xiang xue*
Proportions of components used to make the rice wine (kg)				
Glutinous rice	144	144	144	100
Wheat koji	22.5	25	25	10
Seed mash	8–10	8–9	15	
Acidified rice-steeping water	84	50	50	
Freshwater	112	68.6	100[a]	
Distilled spirit		5		100[b]
Composition of rice wines				
Specific gravity	0.992	0.995	1.0349	1.073
Ethanol (%, v/v)	15.6	17.8	16.7	19.4
Extracts (g per 100 ml)	3.325	4.450	15.65	24.44
Sugar (g per 100 ml)	0.38	0.78	6.50	20.00
Total acids (g per 100 ml)	0.48	0.46	0.46	0.28
Volatile acids (g per 100 ml)	0.06	0.027	0.054	0.056
Nonvolatile acids (g per 100 ml)	0.42	0.43	0.406	0.22

[a]This is yuan hong wine.
[b]This is 50% distilled spirit.
Adapted from Xu G and Bao TF Grandiose survey of Chinese alcoholic drinks and beverages (http://www.sytu.edu/zhgjiu/umain.htm).

(*S. cerevisiae*) in the prepared jiuqu. The actual number of types of jiuqu used for the production of alcoholic beverages in China is unknown. However, there are three broad types of jiuqu, based on the raw material used, and within each broad type there are subtypes based on the color, presence of additives, and size of the molded masses or molded pancakes produced. The names of various jiuqus based on the raw materials rice and wheat are in Table 6. One is also made from wheat bran, called “fu qu,” that is used for alcohol production. The manufacturing processes also vary which also influence the resulting jiuqu. These processes include the use of pure or mixed cultures, a high temperature or a medium temperature, incubation of jiuqu in a thin or a thick layer, hanging in the air in a suitable small container, and wrapping the jiuqu in straw. Consequently, for a given mass of jiuqu, the enzyme activity varies widely. In addition, jiuqu is prepared to suit the product to be manufactured.

Shenqu Historically, the most active wheat-based jiuqu for making rice wine, was “shenqu.” It was made by milling wheat, splitting it into three portions, one of which was roasted, another steamed, and the other left uncooked. The three portions were then mixed thoroughly with added water to a consistency that was less than a slurry. The mixture was transferred to an incubation room, and spread on the floor. Moisture content and temperature were critical and these were managed by opening windows to lower temperature and heaping the mixture to raise temperature. The first three days required high-moisture content, to promote growth of mycelia, and lower-water content was required for the subsequent incubation period up to 49 days. After this time, the shenqu had a yellowish to yellowish-green color. The primary fungi for this preparation were *Aspergillus* species and pure cultures have been isolated and are now used.

Preparation methods today with pure cultures differ from the traditional method in that incubation may be on the floor, as in the traditional method, or in a compartment similar to the germinating compartment used for malting barley, or in trays similar to koji trays. Using the compartment, the steamed, cooked wheat grits are inoculated with fungal spores and piled in a heap for 3 h. The wheat is then spread in a 30 cm layer over the perforated plate in the compartment. The temperature and moisture content are controlled, and oxygen supplied for the fungi deep in the pile, by blowing air suitably conditioned for temperature and water content through the layer. Generally, the temperature is kept to a maximum of ~30°C.

Daqu Daqu, meaning “large qu,” is used for the manufacture of some Chinese spirits and its manufacture is different from shenqu. There are two basic kinds, depending on the temperature reached during manufacture. One kind is high temperature that is allowed to rise above 55°C, perhaps as high as 65°C, and the other is kept below 55°C. The raw materials are wheat flour, barley flour, and pea

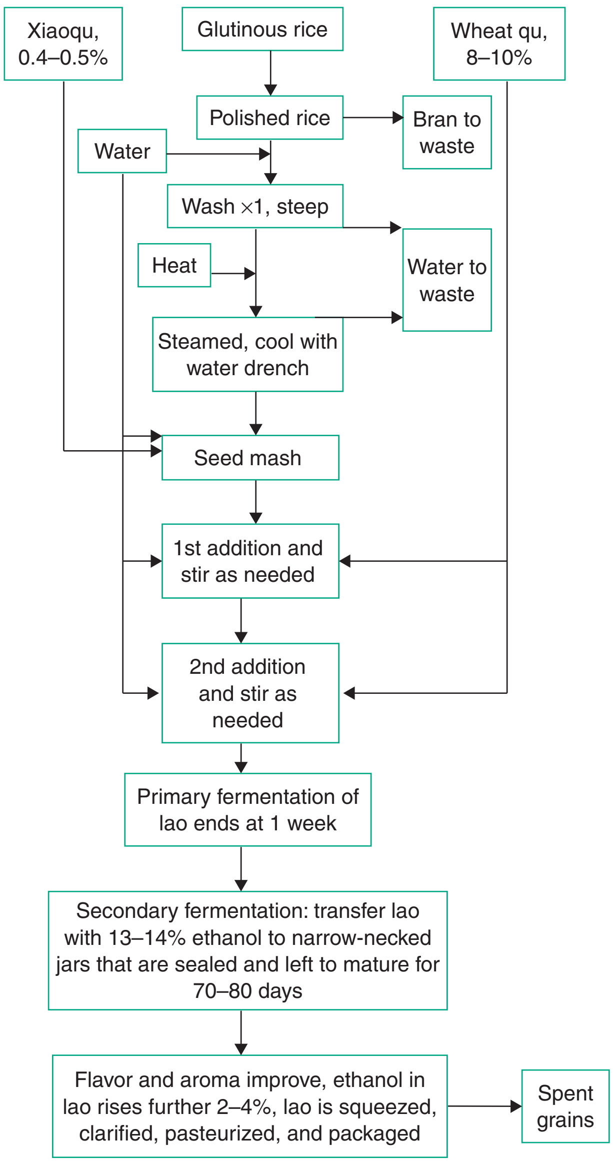

Figure 3 The production of a Chinese rice wine. The name "lao" is equivalent to moromi in saké manufacturing. In this case, there is a secondary fermentation in which the lao is put into a jar and sealed up for months to allow the production of flavors and aromas.

flour mixed together in proportions, depending on the manufacturer. One manufacturer, Yanghe Distillery, uses the following proportions and procedures. The wheat : barley : pea proportions are 5 : 4 : 1. The moisture content is brought to ~40% and the resulting dough kneaded and eventually packed into a wooden mold with dimensions of ~195 × 138 × 75 cm. Traditionally, the packing was done by human treading by ten people with a gradation in body weight to get the dough at just the right firmness in the mold (Figure 4). In modern production systems, mechanical pressing devices are used to prepare the blocks. The block is then removed from the wooden mold and placed in the incubation room, with other blocks, in two layers on bamboo rods giving a space of 2 cm between the layers covered with straw. Incubation is for ~4 weeks and has three phases. In the first phase of ~9 days, there is a rapidly rising temperature due to the growth of fungi and yeasts. The dominant fungi are *Aspergillus* species and *Rhizopus* species, namely *R. oryzae* and *R. chinensis*. The humidity is initially high and is reduced by opening windows. The temperature of the whole batch is controlled to the temperature range 30–45°C by turning and rearranging blocks ~6 times in the 9-day period. In the second phase, of ~8 days' duration, the temperature of the batch is allowed to rise smoothly a little further but within the range 30–45°C. In this phase, more of the moisture evaporates and its loss is controlled so that it is not lost too quickly. In the third phase, the room temperature is allowed to decline and moisture loss from the blocks allowed to increase so that they weigh less. If at the end the moisture has not been reduced to ~12%, the blocks are piled and recovered with straw to raise the temperature and accelerate moisture loss.

Xiaoqu A further important jiuqu is "xiaoqu." The traditional method is similar to that used for daqu production except only steamed and powdered rice is used, the water used is flavored with steeped herbs, and the freshly made blocks are cut into smaller cubes and formed into balls. Selected old jiuqu is used as a seed culture to inoculate the outer surface of the balls. The old jiuqu is a kind of selected starter culture. As the dominant fungi involved have been isolated, a pure culture method is now used in its preparation as follows. The *Rhizopus* species are grown on rice meal or wheat bran and the yeast, a *Saccharomyces* species, is cultured on an extract of a special jiuqu and harvested by centrifugation. Then the *Rhizopus* culture and yeast concentrate are mixed in a 50 : 1 ratio. This mixture is used to make a seed mash for rice wine. This particular approach to rice wine making significantly reduces the time to make the wine.

Chinese Rice Wine Making

Although Chinese rice wines are usually made with rice, they are also made with maize and millet. When made with rice, ~230 kg of rice wine is produced from 100 kg of rice. The jiuqu in rice wine manufacturing has two functions: to supply amylolytic enzymes and to supply yeast for ethanol production. In some modern production systems, commercially manufactured enzymes are used to carry out the saccharification

Table 6 Types of Chinese qu, based on the base grain employed to make alcoholic beverages from rice and other grains

Rice		*Wheat*	
Qu name	*Comment*	*Qu name*	*Comment*
Xiao qu	White, small dimension, made with *Rhizopus* spp.	Mai qu	Wheat qu, made with *Aspergillus flavum*
Yao qu	Herbs added	Da qu	Dimension large
Bai qu	White	Shu mai qu	Wheat steamed or roasted
Hong qu	Red color, due to *Monascus* fungus	Seng mai qu	Fresh wheat used
Hei qu	Black, due to *Aspergillus niger*	Bing qu	Pancake shape
Wu yi hong qu	Red and black color	Dou qu	Added pea or bean, and rice or wheat flour

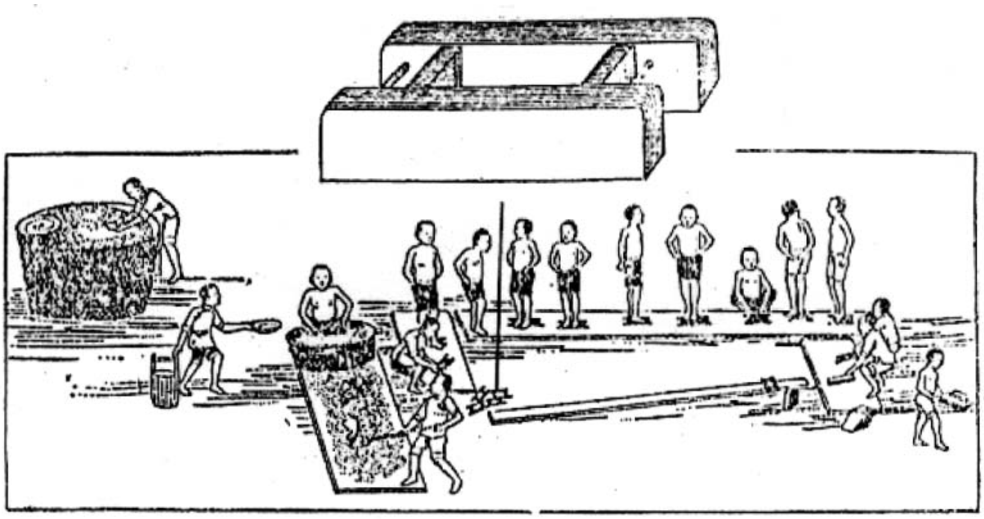

Figure 4 An ancient image of daqu production in China. In the early stage, the "dough" is shaped into rectangular blocks by men pressing the dough into a mold with their feet. The weight of the men pressing a block progressively increases. The block is then managed to encourage mold and yeast growth, before drying the blocks. (Data from Xu G and Bao TF Grandiose survey of Chinese alcoholic drinks and beverages (http://www.sytu.edu/zhgjiu/umain.htm))

step. For various types of wines different portions of ingredients are used (Table 5).

One of the ingredients in the mix is traditional seed mash, and the ingredients used to make this seed mash are 125 kg of glutinous rice that is soaked for several days and then steamed. The steamed rice is then spread in a ceramic vat and after it cools to ~27–30°C, half of the xiaoqu jiuqu is mixed through the rice (Figures 3 and 5). The rice is then stacked around the sides of the vat to form a hollow in the middle of the rice and the rest of the xiaoqu powder is sprinkled onto the surface (0.187–0.25 kg total). This maximizes the surface exposure to encourage growth of *Rhizopus* species (that produce lactic and fumaric acids) to lower the pH, discourage the growth of undesirable organisms, and encourage yeast growth. In addition, the amylase and glucoamylase in the jiuqu saccharify the rice. After about 2 days a pool of liquid containing sugars, etc., gather in the hollow. Then

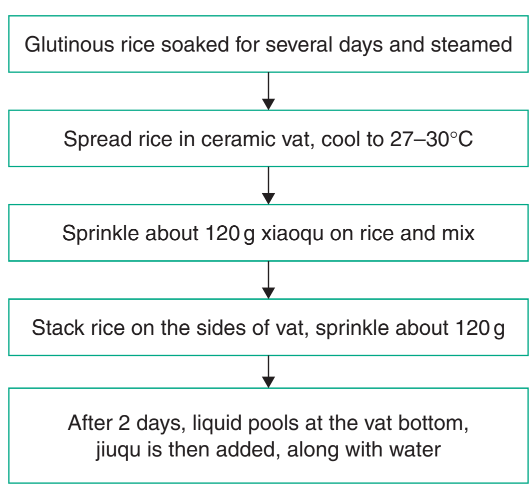

Figure 5 The production of seed mash used in the manufacture of Chinese rice wines.

19.5 kg of jiuqu is added, mixed through the fermenting rice mix and freshwater added to bring the total water content, including that taken up by the rice during steeping and steaming, to 230 kg.

Water and Acidified Rice Steeping Liquid

The water used in wine brewing should have a hardness in the range of 2–6, ~pH 7, and should have a low-iron content. The acidified rice-steeping liquid is traditionally prepared by steeping the polished rice in the water for periods of 10–20 days, preferably 13–20 days. During the steeping, lactic acid bacteria grow and lower the pH. This traditional liquid, when added to the final brew, helps to inhibit the germination of bacterial spores and growth of vegetative cells, provides amino acids and vitamins, lowers the pH for yeast growth, and helps improve the flavor of rice wines. However, alternatives to this include using diluted vinegar solution or a broth made with wheat flour, but lactic acid is now commonly added (*see* **Fermentation**: Origins and Applications).

Chinese Distilled Liquors

Chinese distilled liquors are classified according to the jiuqu used, the type of aroma and flavor developed, the fermentation state for ethanol production, the quality, the ethanol content and the raw materials used. Important types are in Table 7 along with the characteristic flavor impact compounds. Many Chinese liquors are based on sorghum and contain 53–55% ethanol. They have characteristic aromatic fragrance due to the presence of 4-ethylguaiacol, vanillic acid, and vanillin. The hexanoic acid needed to result in ethyl hexanoate comes from the metabolic activity of anaerobic bacteria in the fabric of the fermentation pits. A difference between Chinese-distilled sorghum liquor and Western-distilled grain liquors is the use of external mold enzymes from koji-like products.

The production processes vary (*see* **Beverages**: Distilled). For rice spirit, the rice is washed, steamed, cooled, inoculated with xioaqu, and placed in a ceramic vat to allow the enzymes to breakdown the starch. Then water is added and the vat covered for 7 days to allow yeast growth and then the fermented liquid is distilled. For sorghum, the grains are crushed, mixed with hot water, steamed, cooled, and further water added. Daqu is added to the cooled mixture in a ceramic vat or mud pit or stone pit and sealed. The fermentation is allowed to proceed for 3–4 weeks and the steamed sorghum husks added and the mixture distilled. The spent sorghum is then remixed with daqu and sealed in a vat and left for 3–4 weeks whereupon steamed husks are added again and the mixture distilled again.

Table 7 Some of the jiuqu mold preparations used in the manufacture of Chinese distilled liquors and the names of liquors based on distinctive aromas and flavors and their characteristic flavor impact compounds

Jiuqu used	*Aroma and flavor*	*Flavor-impact compound*
Daqu	Maotai	
Xiaoqu	Luzhou	Ethyl hexanoate and ethyl butyrate
Fuqu	Fen	Ethyl acetate
	Rice	Ethyl lactate and ethyl acetate

The production system in Taiwan is of rather shorter duration. The typical “wine cake” (or juiqu) for spirit production is produced with cracked wheat, contains up to five varities of yeasts (including *S. cerevisiae* and *S. fibuligera*); four molds (including *Mucor* and *Rhizopus* species); and six types of bacteria, including a *Clostridium* species. The level of activity of hydrolytic enzymes is usually low.

The steamed sorghum is spread out on the floor to a thickness of ~5 cm and powdered wine cake mixed through it. The moisture content of the sorghum is ~55%. The fungi grow on the cool and dry surface, whereas bacteria and yeasts grow within the wet mass of sorghum. After 24 h, the sorghum is piled into heaps that encourage growth of yeast in an anaerobic and warm environment (prefermentation). The size of the pile is restricted because the internal temperature of the pile must not be allowed to rise above 40°C, and the heat produced metabolically is not easily dispersed. The Taiwanese put the inoculated sorghum into stainless steel tanks or boxes and cover them with polythene sheet to prevent moisture loss and reduce aeration. Microbial growth and metabolism is allowed to progress for up to 10 days after which the mixture is put through a steam distillation to remove the ethanol. The pile of sorghum is reinoculated to encourage further growth and when ready the sorghum is distilled again. Each heat treatment, or steaming, causes partial hydrolysis of starch, carbohydrates, and protein. Steaming also removes the alcohol that prevents yeast cell growth in the thin film of water surrounding sorghum grains. Alcohol is collected by condensation of the distillate and the ethanol yield is ~22.53 kg per 100 kg of sorghum.

Microbial cells grow slowly on sorghum due to low availability of fermentable substrates, and this leads to the production of secondary metabolites mentioned above, which contribute to the characteristic strong aromatic fragrance of sorghum liquor.

In mainland China, the production of sorghum liquor is much more complex and it takes about 1 year

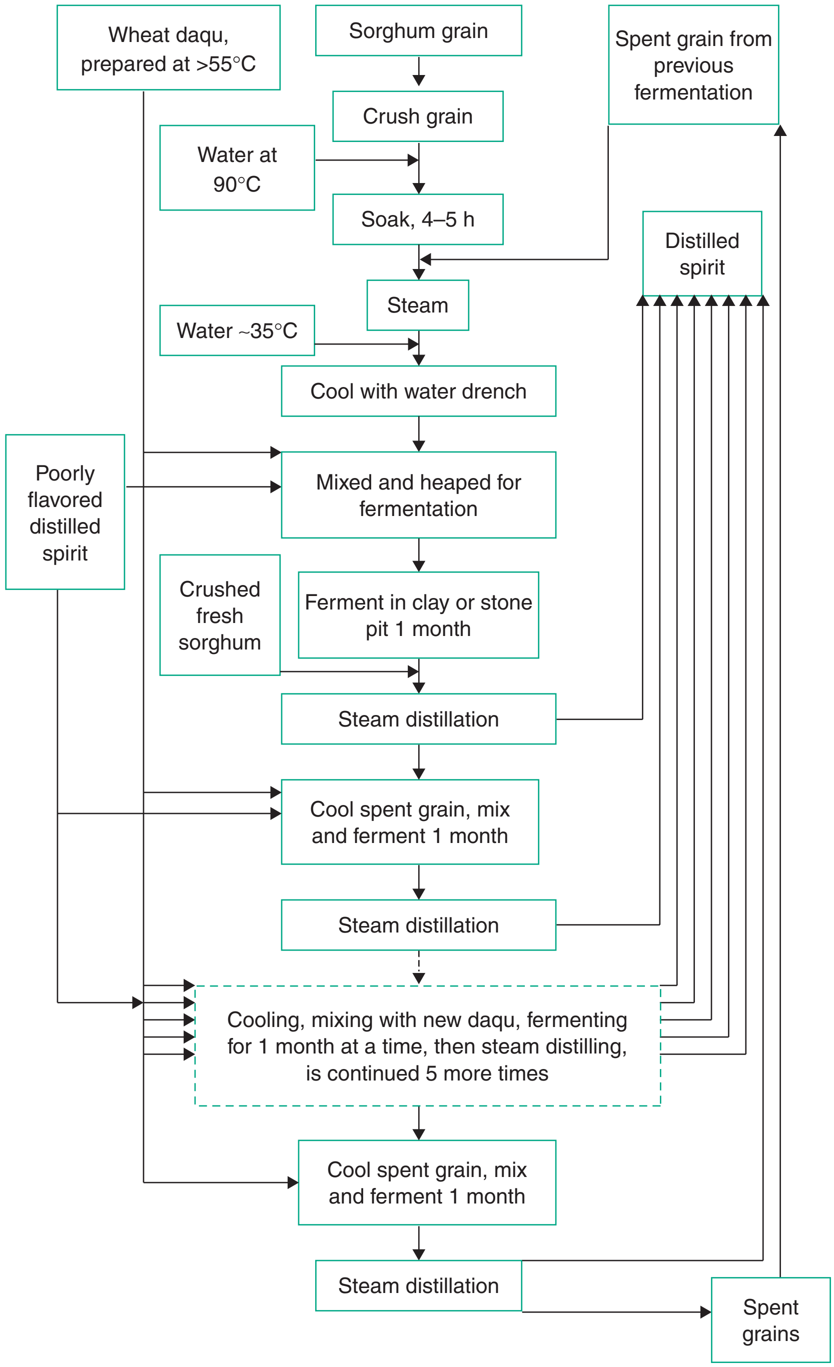

Figure 6 The traditional Chinese method of preparation of sorghum-based distilled liquors. The amount of daqu and sorghum used is ~1 : 1. The traditional pit used for the fermentation is the source of particular flavors for some liquors due to associated bacterial activity. Eventually, the completely spent grain is discarded.

to complete the distillations. The process begins with sorghum that is crushed, soaked in hot water, spent grain from a previous fermentation added and then the entire mix is steamed. Spirit of lower quality and the inoculum of daqu is added to the cooled mixture (Figure 6). It is heaped to allow the fermentation to begin and then placed in a fermentation pit for up to a month to allow the fermentation process to take place. The mixture is then steam-distilled, more daqu added, and the fermentation conducted all over again. With slight variation the process is conducted up to 8 times.

Distilled

G H Palmer, Heriot-Watt University, Riccarton, Edinburgh, UK

Introduction

Distilled beverages that are sold commercially are produced from plant materials (Table 1) and their

Table 1 Raw materials used for the production of some major distilled beverages

Products	*Raw materials*
1. Scotch malt whiskies[a]	100% malted barley
2. Scotch grain whiskies[a]	Wheat or maize (+ malted barley)
3. Cachaça	Sugar cane juice only. Unlike “industrial” Cachaça, which is made from cane products (e.g., molasses) and sugar, only fresh sugar cane juice is used to produce traditional, “artesanal” Cachaça
4. Rum	Molasses mainly and sugar cane juice
5. Irish whiskies	100% malted barley
	Barley + malted barley
	Maize + malted barley or enzymes
6. Gin	Maize or wheat (with malted barley or enzymes for starch conversion into sugars). Pot still distillation of Juniper berries and other botanicals or, addition of spirit to Juniper berries and botanicals or to the essence of these plants
7. Tequila (100%)	Agave (*Agave tequilana* Weber Var. Azul) plant
Tequila	Agave plant + sugar or syrup
8. Vodka	Cereals, grape juice, raisins, molasses, potatoes (with or without enzymes for starch conversion)
9. American whiskies (bourbon, corn, rye, Tennessee)	Maize + rye (with malted barley: plus or minus commercial hydrolytic enzymes)
10. Canadian whiskey	Maize, rye, and malted barley and malted rye + amylolytic and glucanolytic enzymes
11. Brandy	
Cognac	Grapes
Armagnac	Grapes
Eau de vie	e.g., pears, raspberries, cherries, and plums
12. Aquavit	Grain or potato (with malted barley or enzymes for starch conversion). Neutral spirit from grain or potato is then redistilled with flavorings. Caraway is the main flavoring and citrus peel. Cardamom and anise can be incorporated as well

[a] Japan also produces malt and blended whiskies.

Table 2 Types of stills used in production of distilled spirit beverages

Products	*Stills*
1. Scotch malt whisky	Usually, two large copper pot stills (wash and spirit) – tube condensers
2. Scotch grain whisky	Continuous (patent) still (analyzer, rectifier)
3. Cachaça	Small copper pot stills with worm condenser coils. Traditional (e.g., "artesanal") Cachaça is produced using pot stills. Single distillation like Aramagnac. Continuous stills used to produce "industrial" Cachaça
4. Rum	Continuous still (Analyzer, rectifier) – Puerto Rican (light rum). Distillation in series of two or three copper pot stills (to avoid double distillation in one still). Cooling coil condensers present: Jamaican (high flavor (heavy) rum)
5. Irish whiskey	Three copper pot stills (viz: wash, low wine, and spirit). Triple distillation
6. Gin	Continuous still (analyzer, rectifier) then copper pot stills for distillation with botanicals
7. Tequila	Copper pot still (double distillation) or Continuous still (analyzer, rectifier)
8. Vodka	Continuous still (analyzer, rectifier)
9. American whiskey	Continuous stills or continuous still plus doubler for additional distillation
10. Canadian whiskey	Continuous still with analyzer column, extraction column, and rectifying column. Pot stills
11. Brandies	
Cognac	Small copper pot still with cooling worm, direct fired instead of internal heating coil. Double distillation
Armagnac	Small copper pot still or small single column continuous still. Single distillation in pot stills, like traditional Cachaça
Eau de vie	Copper pot still – double distillation (analyzer, rectifier)
12. Aquavit	Continuous still (analyzer, rectifier)

distillation processes (Table 2) are clearly defined. Each product has distinct aromas and flavors which reflect raw materials, distillation process, and post-distillation treatments such as maturation in wooden (e.g., oak) casks. The flavor compounds in distilled beverages are referred to as congeners. Different beverages can have small differences in congener levels but have large differences in flavor and aroma intensities. Flavor and aroma intensities may also relate to the complex modulating effects, which different congeners have on each other, and to the physiological and cultural differences of consumers. In distilled spirit beverages, ethanol is the main compound as regards quantity and the congeners can be regarded as "ancillary products" of the natural production of ethanol.

Ethanol of distilled beverages is produced from the different sugars derived from the raw materials used. The mechanisms of production of congeners are very complex. Some are produced by yeast during fermentation, others are produced during distillation, and some develop during maturation. In some distilled beverages such as gin, flavor materials are added. The term "distilled portable spirits" relate to distilled products that are eventually packaged and sold as beverages for human consumption (Tables 1 and 2). The production procedures of many distilled beverages are defined by law. For example, Scotch whisky means whisky distilled and matured in Scotland and Irish whiskey means whiskey distilled and matured in Ireland. Scotch malt whisky is made from malted barley. The blended brands of Scotch whiskies are blends of Scotch malt whiskies and Scotch grain whiskies. Scotch malt whiskies are produced in pot stills and Scotch grain whiskies are produced in continuous patent stills. Only enzymes from malted barley can be used in Scotch whisky production. In the United States, bourbon whiskey must be produced, from a mash conversion of not less than 51% corn grain and rye whiskey must be produced from not less than 51% rye grain respectively. Cognac or tequila can only be made in respective areas of France or Mexico. In many countries, a minimum age of post-distillation maturation in wooden barrels is designated by law. Also, in this regard, Scotch whisky can only be matured in Scotland in oak barrels and bourbon can only be matured in "new" (charred) oak barrels in the United States of America.

Historical Background

The exact dates of development of many distilled beverages are not known. The Chinese may have developed the distillation process in ancient time. The ancient Egyptians had alembics which could have produced alcoholic drinks but it was the Moors who were responsible for distributing the technique and for the derivation of the word "alcohol" which is derived from the old Arabic word "Al-Kuhl." The distillation process is therefore an ancient-world technology and is known to produce a concentrated alcoholic essence of the initial ferment, which contained lower levels of

ethanol. A sugar solution of ~14–16% will, after fermentation by yeast, yield ~7–8% ethanol. According to Gay-Lussac, 100 lbs of glucose should, after fermentation by yeast in ideal conditions, yield 48.89 lbs of carbon dioxide and 51.11 lbs of ethanol. But, according to Pasteur, only ~95% of these products can be expected in fermentation systems. Ethanol is a simple alcohol. It is a member of a large group of alcohols, some simple, others complex, but all containing carbon, hydrogen and oxygen, and hydroxyl groups, which have replaced hydrogen atoms.

Although it has been suggested that the Crusaders brought the technique of distillation to Europe in the eleventh to twelfth centuries, it was not long after this period that distillation activity was discovered in Ireland. The first written record of Scotch malt whisky appeared in 1494. The word whisky is spelt "whisky," when applied to Scotch but is spelt "whiskey" when applied to Irish, Canadian, and American whiskies. In 1931, the Coffey (continuous or patent) still was invented by Aeneas Coffey to produce Scotch grain whisky in large quantities. The first blended Scotch whiskies (i.e., mixtures of malt and grain whiskies) were produced by Andrew Usher in 1860. Blended whiskies are now ~93% of the Scotch whisky market worldwide.

Although the production of vodka, in Russia, dates back to the twelfth century, significant development of other major spirit beverages such as tequila (Mexico), Cachaça (Brazil), and cognac (France) took place in the sixteenth century. A large rum industry, operated by slaves in the West Indies, was very productive in the seventeenth century. Gin was being produced in Holland in the seventeenth and eighteenth centuries. By 1743, the annual consumption of gin in Britain was 70 million liters (Ml) for a population of 6 million people. The devastating effect of excessive drinking of gin was portrayed in Hogarth's (1697–1764) famous etchings of gin drinkers. American whiskies developed in the eighteenth century and Canadian whiskey appeared in the nineteenth century. Canadian rye whiskey came to prominence in the 1940s. Examples of other localized, smaller-volume products of the distilled spirit market are: aquavit (Denmark), arrack (e.g., Turkey), grappa (Italy), marc (France), okolehao (Hawaii), ouzo (Greece), pisco (South America, e.g., Chile and Peru), mao tai (China), and mezcal (with or without "worm" (Mexico)).

As regards the science and technology of distillation, the first study of the distilling process, where a liquid containing many compounds is vaporized, separated, and collected as desirable (drinkable) was made by the French alchemist Arnold de Villeneuve in 1310. Taxation of distilled spirits is an important source of revenue for many producing countries. For example, the first taxation on Scotch whisky was in 1644 at ~40 pence per gallon. That taxation persists today at the impressive figure of about £88 per gallon for pure alcohol. Of all the spirits in the world, vodka sells in the largest volume. Bacardi rum is the largest brand. Scotch whisky earns the largest income of the brown spirits and Cachaça is the spirit product that is consumed in the largest volume in one country (Brazil). It is produced in the largest number of production facilities (*c.* 18 000).

Malting and Mashing Processes

Malting

Scotch malt whisky is produced from malted barley of known varieties. Malted barley is derived from the malting process (**Figure 1**). In this process, ~25–500 t of barley are steeped in water and air-rested for ~48 h at ~16°C. The water is drained and the grains allowed to germinate (grow) for a period of ~5 days at 16–18°C. The germinated grains are then kilned (dried) at 60–70°C. During kilning, peat may be burnt to "peat" the malt because the

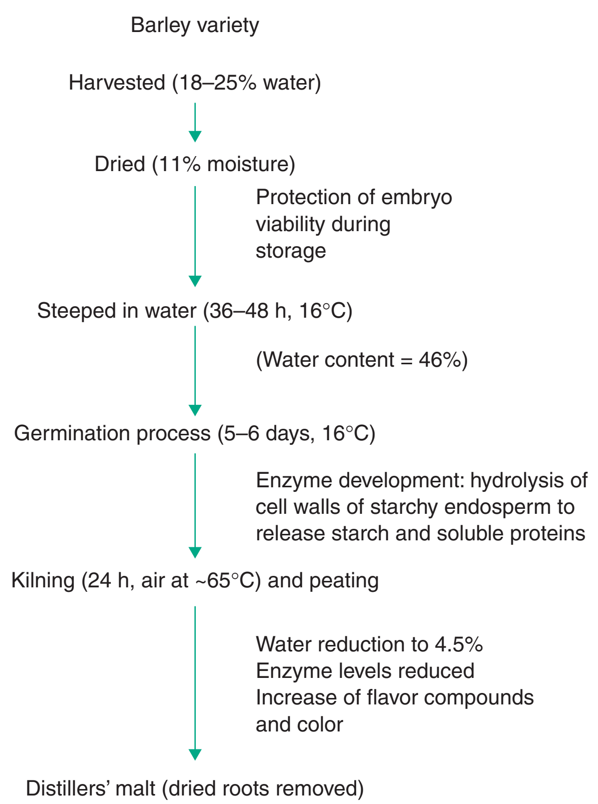

Figure 1 Production of the distillers' malt.

smokey-peaty (phenol: 0–50 ppm) flavor of malted barley is an important flavor note of many brands of Scotch whiskies.

During the germination process, the plant hormone gibberellic acid is produced in the growing embryo. This natural hormone is transported to the aleurone (bran) layer which encloses the starchy endosperm (Figure 2). The aleurone is induced by the hormone to synthesize endosperm-degrading enzymes such as cell-wall-degrading endo-β-glucanases; storage-protein-degrading proteases and starch-degrading α-amylases. Other enzymes such as β-amylase (maltose producing) and carboxypeptidases (amino acid producing) develop in the starchy endosperm. Together, these enzymes modify (disrupt) the starchy endosperm so that subsequent milling and extraction (mashing) of the malt in hot water can occur readily. During this process, starch is converted into fermentable sugars, amino acids are extracted and produced. Vitamins and minerals are also extracted. These substrates are required, by growing yeast cells during fermentation, to produce ethanol and flavor compounds (Figure 4).

Distillers set laboratory specifications as regards the quality of the malt they require to produce their whisky products. For example, such malts must have a high fermentable extract potential of ~68% and fermentability potential of ~87%, amino acids (free amino nitrogen) should be 130–140 ppm and the modification of the malt, assessed in terms of friability should be at least 90% to enable easy milling and extraction.

Nitrosamines and ethyl carbamate are natural carcinogenic compounds, which develop during the kilning and distilling processes respectively. Very low levels of nitrosamines are specified (none or 1 ppb max.). Glycosidic nitrile is also specified at very low levels (3.0 g t^{-1} of malt) because it is the precursor of ethyl carbamate. Only malted barley can be used to produce Scotch malt whisky. In Scotch malt or grain whisky production, all the enzymes required to convert the starch and proteins to sugars and amino acids must be derived from the malt. By law, no extraneous enzymes can be added.

The Mashing Process – The Starch Degradation and Sugar Extraction Process

Cereal grains (Tables 1 and 3) used in whisky (whiskey) production contain significant quantities of starch and cell wall polysaccharides such as β-D-glucans and pentosans.

Cooking solubilizes both the large (10–30 μm) and small (< 5 μm) starch granules (Figure 3). Heating of raw starch granules beyond their gelatinization temperatures is necessary before they can be converted optimally into sugars by amylolytic enzymes. The large starch granules of wheat, barley, and rye, gelatinize between 63°C and 65°C. The gelatinization temperature of rye starches can extend to 70°C. Small starch granules will gelatinize at ~80°C. Maize and sorghum starches (10 μm) gelatinize above 70°C, and are usually cooked. Malt also contains starches which must be gelatinized to realize the extract that malt can contribute to the mash. Therefore, when

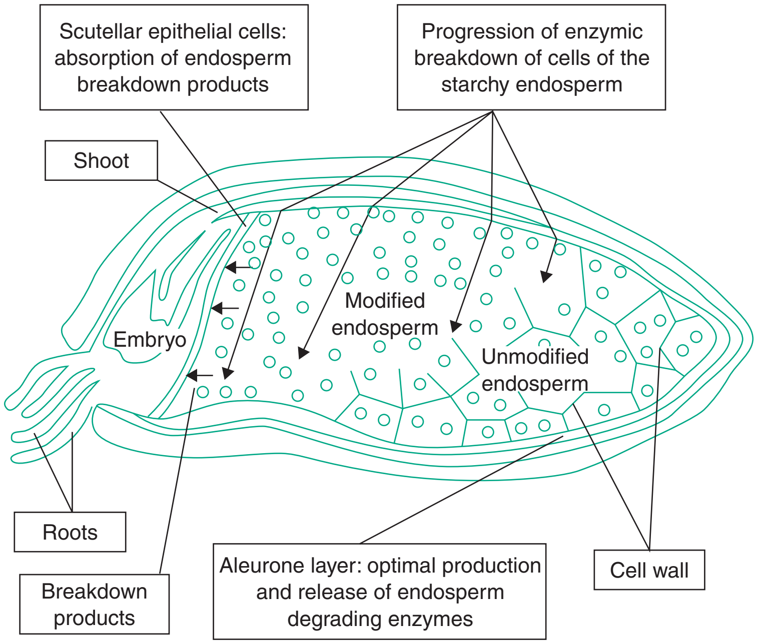

Figure 2 Progression of endosperm breakdown by endosperm-degrading enzymes during the malting process (×34).

Table 3 Constituents of some cereals (%)

Cereals	*Starch*	*Gelatinization temperature (°C)*	*Protein*	*Lipid*	*β-D-glucan*	*Pentosan*
Barley	65	63	10.0	3.0	3.5	9.0
Wheat	64	60	11.0	3.0	0.5	8.5
Rye	60	65–70	13.0	2.5	1.5	9.0
Maize	70	>70	11.0	5.0	0.3	3.5
Sorghum	70	>70	10.0	3.0	0.3	3.0

malt is being used to convert cooked or gelatinized starch, the mashing temperature must be between 63°C and 65°C, temperatures at which malt starches (i.e., large starch granules) will gelatinize.

Malt contributes starch degrading enzymes such as α-amylase, limit dextrinase, and β-amylase during mashing. α-Amylase liquefies gelatinized starch molecules, β-amylase hydrolyzes these molecules to maltose – the main sugar of cereal-derived worts. Malt is an important source of amino nitrogen which yeast requires not only for growth but also for the production of flavor compounds. Shortage of amylolytic enzymes in the mash can be corrected by adding commercial amylolytic enzymes, if permitted. Malt contains vitamin B and phytic acid. The latter helps to cause an acidic pH during mashing which favors the activities of amylolytic and protolytic enzymes. Amino acids also add buffering capacity to the wort. Unmalted cereals also contribute amino acids and small assimilable peptides to the wort, albeit at significantly lower levels than malted barley.

Scotch whisky By law, only the enzymes of malted barley can be used to convert (hydrolyze) the starches of all malt mashes for malt whisky production and the enzymes of cooked maize or wheat used for grain whisky production. Whole grains of maize or wheat are cooked at ~140°C under pressure. Grits of maize or milled wheat are cooked at ~105°C under pressure. After these cereals are cooked and then cooled to ~63°C, a slurry of 9–10% milled green or dried malt is added to effect starch conversion into sugars.

The sugary wort required for Scotch malt whisky production is derived from a mash of 100% milled malt (e.g., 8–10 t). The malt is mashed in a water : malt ratio of ~4 : 1, at 63–64°C for at least 1 h. After the sugary wort is "run-off," the malt bed is washed, 2 or 3 times with hot water (80–100°C) to ensure that all the fermentable sugars are extracted.

Although some grain distilleries collect and ferment the sugary worts, others ferment the entire mash. To start the fermentation process, yeast is added to cooled worts (20°C) or to cooled unfiltered maize-malt or wheat-malt mashes (20°C). About 50% of the fermentable sugars of distillers' sugary worts are maltose. This sugar is mainly produced by β-amylase during mashing. However, α-amylase and limit dextrinase enzymes also assist in the hydrolysis of gelatinized (cooked/heated) starch – these enzymes facilitate the activity of the β-amylase enzyme. β-Amylase is more heat labile than α-amylase. β-D-glucans are present in the cell walls of the endosperm. Barley contains ~3.0% β-glucan. Malt should contain less than 0.4% β-glucan to ensure that during mashing, wort "run-off" rate and starch release are optimal. Cell wall β-D-glucans and pentosans can limit water removal from spent grains required for animal feed production. Appropriate treatment of spent grains with β-glucanase assists dewatering.

Irish whiskey In Ireland, a mash can contain only malt for malt whiskey production or the mash may have 60% of hammer-milled barley and 40% malt or it may comprise 90% hammer-milled maize and 10% malt. The 10% malt may be replaced by hydrolytic enzymes. Commercial enzymes can only be added to the production of grain whiskey. The different spirits

produced are used to produce a wide range of distilled products such as malt whiskies or blends of malt and grain whiskies made in pot stills or continuous stills.

American whiskies Bourbon must be produced from a mash of not less than 51% corn but typically a bourbon mash contains ~70% corn, 15% rye, and 15% malted barley. A rye whiskey mash can contain 51% rye, 39% corn, and 10% malted barley. Tennessee whiskey can be made from a mash of 80% corn, 10% rye, and 10% malt. Different milling systems are used to mill the raw grain. The milled grains and malt or enzymes are heated and cooked and then cooled. An additional quantity of milled malt is mashed in at temperatures not exceeding 64°C. Highly enzymic malts are used. The quantities added are usually lower than those used in Scotch grain whisky production. During mashing, natural enzymes of the malt and commercial enzymes produce optimal conversion of starch to sugars. Conversion (mashing) time varies from 15 min to 60 min. The term, "sour mash," describes the acidic nature of the mash. Long mashing times can encourage the development of microbial infection. At the end of the mashing process, the mash bed (spent grains) is washed with hot water to optimize sugar release, as in other whisky-making processes.

Canadian whiskies For Canadian whiskey, maize grains are milled and cooked at 140°C. The mash is cooled to 100°C and amylase is then added. Malts containing amylases and commercial amyloglucosidase are added at 63–65°C to optimize fermentability. For Canadian rye whiskey, the mash contains milled rye alone or more commonly, rye and other cereals such as maize and/or wheat. Heat-stable amylase and β-glucanase enzymes are added as the mash is heated up to ~85°C where the grain meal is held for ~20 min. It is then cooled to 63–65°C and amylases and amyloglucosidases are added to give optimal release of sugars. Finally, the mash is cooled and yeast is added. Fermentation starts at 20–30°C. Yeast may have been subjected to lactic souring.

Gin and vodka The spirits used for the production of gin or vodka are usually neutral spirits. These are mainly highly distilled ethanol (minimum 96%) and are almost free of congeners. The main flavor product is ethanol. The lowest limit of ethanol for neutral spirit (96%) is usually higher than the 94% taken for the production of Scotch grain whisky. In this regard, Scotch grain whisky has more flavor congeners than the spirits used for gin and vodka production. Neutral spirits are produced from mashes of milled/cooked cereals, potatoes, molasses, fruits, or sugars. Mashes containing cereals and potatoes require the addition of malt enzymes or external enzymes to convert starches into sugars as described for whisky/whiskey production.

Cachaça For traditional Cachaça, e.g., "artesanal," no mashing process is necessary because the fermentation sugar, sucrose, is squeezed from washed, freshly harvested, stems as sugar cane juice. Many varieties of sugar canes are used; some reflect crosses of standard varieties such as *Saccharum officinarum* L. with other varieties. Sugar content of the juice is ~12–16%.

Rum The fermentation sugar, sucrose, is derived primarily from high or low sugar molasses. Sugar cane juice is also used. Molasses have a higher mineral and nitrogen content than sugar cane juice and impart a different flavor to the final product. Molasses of high sugar content (~22–24% sucrose), tend to produce a spirit of 10–12% ethanol, whereas sugar cane juice (12–16% sucrose) tends to produce a post-fermentation alcohol content of ~6–8% alcohol. Rum produced from sugar beet molasses gives a very different flavor from rum produced from sugar cane molasses. Tasting trials showed that the sugar cane product is generally preferred.

Tequila Tequila and mezcal (with or without the "worm" in the bottle) are both produced from the Agave plant. However, tequila is produced in Tequila and its vicinity from *Agave tequilana* Weber var. Azul, whereas mezcal is produced from *Agave patatorum*. Agave head is harvested and cut into pieces for cooking. During cooking, inulin polymer is hydrolyzed to produce fructose which is sweeter than sucrose – this process can take 2 days. Autoclave cooking will produce a sugar syrup of ~10%. The cooked agave is milled in small sugar cane mills and the milled product and sugary juices are collected.

For the production of 100% tequila, only agave sugar can be used. For other kinds of tequila, cane sugar, molasses, or corn syrups can be added to levels of 49%. The sugary worts used to produce 100% tequila have sugar concentrations that range from 4% to 10%. For other tequilas, sugar concentration can range from 8% to 16%.

Brandies:

1. Cognac derives its name from the town Cognac. The base wine for cognac production comes mainly from the St. Emillion grape although grapes from Folle Blanche and Columbard are authorized. The glucose sugar of the acidic wine is

fermented without the addition of yeast for 3–5 weeks. The acidic wine is then distilled in small pot stills.

2. Armagnac comes from the Armagnac region and there is written reference to this brandy in 1411, two centuries before cognac was produced. Grape sugar (glucose) is fermented to produce, like cognac, low-alcohol wines. These are then concentrated by distillation without prior removal of grape residues (lees).
3. Eau de vie – soft fruits are mashed (unheated or preheated) and their sugars are converted to alcohol during fermentation. Alcohol is concentrated in pot stills. Eau de vie is associated with the Alsace region. Calvados brandy, which is made from apple mashes, specifically comes from the provinces of Brittany, Normandy, and Maine.

Fermentation

Cereal (malt) worts can have the following composition of sugars and dextrins: fructose 1%; glucose 10%; sucrose 5%; maltose 50%; maltotriose 15%; maltotetrose 6%; and dextrins 13%. Excluding sucrose, these sugars are the products of amylolytic hydrolysis of gelatinized starch during mashing. In contrast, sucrose is the only major sugar of cane juice. In fruit mashes and juices, glucose and sucrose are the major sugars and in tequila mashes, fructose is the dominant sugar. Total sugar levels of distillers' wort range from 10% to 16%. Yeast requires a nitrogen source to effect expected growth from which ethanol and flavor compounds are produced (Figure 4). The raw materials used usually satisfy the nitrogen requirements of the fermenting yeast.

A malt whisky wort can contain $250\,\mathrm{mg\,l^{-1}}$ of α-amino nitrogen, whereas a grain whisky mash of 90% wheat can contain $\sim$100–120 $\mathrm{mg\,l^{-1}}$. In malt whisky production, there is an exceptionally high level of amino acids which may contribute to the production of esters and other flavor compounds. The role of amino acids in the formation of flavor compounds is complex. However, optimal levels of these nitrogenous compounds will assist in optimal production of esters. Suboptimal levels of amino compounds may encourage the production of higher (fusel) alcohols. However, even at optimal levels of amino nitrogen compounds, different levels of esters can be produced suggesting that other factors influence ester production, such as yeast type, wort concentration, lipid content, and fermentation temperature. Special mention is made of esters because they are important flavor compounds that contribute different flavors to distilled spirits. In this regard, the total ester content does not convey the individual or the complementary contribution of different esters to overall flavor. Insufficient nitrogen nutrients can limit yeast growth, resulting in the production of unexpected or undesirable flavors.

One of the main distinctions in fermentation systems is fermenter size. Cachaça and brandies

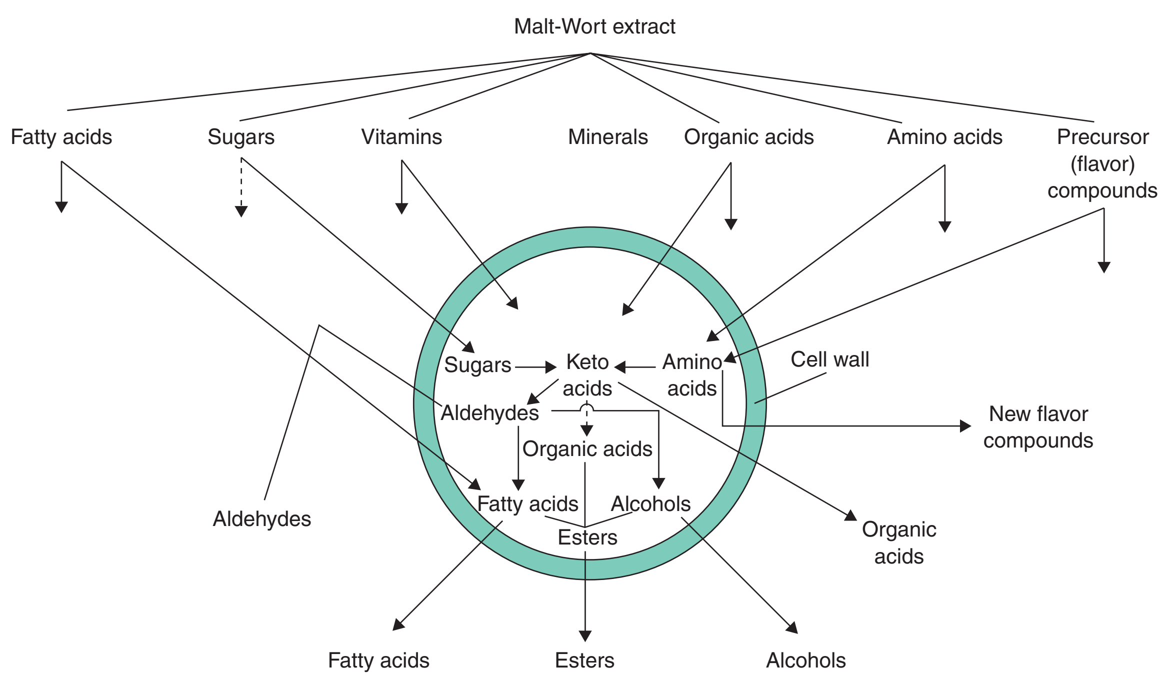

Figure 4 Fermentation: production of low percentage of spirit (6–8%) from plant sugars and nutrients prior to distillation.

such as cognac and armagnac are produced from small fermentation volumes (~1500–3000 l), whereas rum and tequila are derived from larger volumes in the order of 10 000–12 000 l. In malt distilleries, fermentation vessels can range in size from 4000 to 20 000 l. In grain distilleries, these vessels can be as large as 250 000 l. Yeast is usually added to initiate and advance fermentation in gin, vodka, rum, and whisky production. Residual postfermentation yeasts may be used to start new fermentations of spirits such as Cachaça, tequila, and some brandies. However, in cognac, wine is allowed to self-ferment for 3–5 weeks. For "artesanal" Cachaça, naturally trapped yeast is added initially to effect fermentation. In the production of heavy Jamaican rum, natural inoculation is encouraged but can be supplemented by yeast additions. In Scotch whisky production, fresh yeast is added to new fermentations.

Fermentation temperatures vary. Unlike beer fermentation, which usually takes place below 15°C, distillery fermentations range from 20°C to 40°C. Since there is no temperature control, whisky/whiskey fermentations can start at 20°C and rise to 30°C over a short 48 h period of fermentation. Most distillery fermentations are usually completed by 48 h, compared with beer fermentations which can extend to 5 days. However, in tequila and American whiskey production, slow fermentations may exceed 72 h. The high fermentation temperature and the high yeast-pitching rate are mainly responsible for the fast fermentation rates of most of these spirits. Pitching rates for yeast (*Saccharomyces cerevisiae*) vary and can range from ~10 to 20 million cells per ml. Distillers use either residual postfermentation yeast, company-cultured yeast, or purchased yeast to effect fermentation. Yeast under cold storage tends to be more viable that yeast stored at warm temperatures. Although, great efforts are made to control bacterial infection during fermentation, the by-products of the metabolism of lactic acid bacteria and *Clostridium saccharobutyricum* in heavy rum production, can be essential congeners of the expected flavor profile of fermented worts and mashes. In general, during fermentation, sugars such as sucrose, glucose, fructose, maltose, maltotriose, and maltotetrose are fermented to ethanol, and, nutrients (e.g., zinc and amino acids, vitamins, fatty acids), and some malt flavor compounds are used by the yeast to grow and form a wide range of flavor compounds characteristic of the spirit to be produced. These flavor compounds include simple alcohols and higher alcohols (fusel oils), esters, organic acids, aldehydes, ketones, sulfur compounds, and aromatic flavor compounds such as acetals which tend to develop in acid conditions and high ethanol medium.

At the end of the fermentation process, the chemical composition of mashes and worts could be similar. However, intraspirit and interspirit differences become distinct after the distillation process has isolated, separated, and combined the congeners that define particular spirit products. Fermented worts, derived from different raw materials, will produce different spirit products. However, within a product type, differences will be caused by differences in still sizes, shapes, and modes of operation. In this regard, distillation is as important as raw material in defining spirit type and spirit quality. Here, quality is defined as meeting the expectations of the customer.

Distillation

Distilling Using Copper Pot Stills

The fermented worts or mashes of many distilled spirits contain ~6–8% ethanol. The purpose of distillation is to vaporize the compounds present in worts and mashes and effect their separation and concentration. Still size can vary from 5000 to 25 000 l in capacity. Volatile compounds are derived from the contents of the still. New volatile compounds are also formed during distillation. If specific cyanide-containing precursors are present, unacceptable compounds such as ethyl carbamate are produced. Cereal spirits should have an upper limit of 150 $\mu g\,l^{-1}$ of ethyl carbomate; fruit spirits should have no more than 500 $\mu g\,l^{-1}$. Most stills are heated by heating coils. Cognac stills are fired directly. In the production of Scotch malt whisky, double distillation is involved but triple distillation occurs on a limited scale. The situation is similar for rums. For Irish whiskies, triple distillation is standard. Single distillation is also used to produce products such as Cachaça and armagnac. Double distillation usually takes place in wash and spirit stills. The distillate of the wash still (the low wine) is very high in congeners and ethanol is concentrated from 6–8% to ~23%. In the spirit still, the low wine is fractionated into "foreshots" (heads), "middle cut" (spirit), and "feints" (tails). Single distillation pot stills operate in a similar manner to spirit stills, separating the ferment into three factions. After maturation in wooden (e.g., oak) casks, the "middle cut" (spirits) will be transformed into the distilled product (Table 2). In the triple distillation system, as used for Irish whiskey, the late portion of the distillate of the wash still is removed and redistilled in a low-wine still. The early portion of the wash still distillate and the early portion of the low-wine still are added to the spirit still for fractionation in "heads," "middle cut," and "tails." As is the case for spirits such as Scotch whiskies and brandy, the congener

levels of traditional Cachaça are higher than those of rum or bourbon. However, this may not be the case for all "industrial" Cachaça, produced in continuous stills.

The overlap of "foreshots" into the "middle cut" (i.e., the spirit) and the overlap of the "middle cut" into the "feints" can change the expected flavors of the spirit. High levels of "foreshot" compounds in the spirit can be detected by making a 50/50 mixture of spirit and water. If cloudiness develops, the "foreshot" content of the spirit is usually too high and adjustments to the "spirit cut" time should be made. "Foreshots" contain very volatile compounds which can confer "solvent-like" character to the spirit. In contrast, "feints" contain low volatile compounds that give the spirit a distinct stale, metallic odor.

During pot still distillation, ethanol concentration rises during "foreshot" collection but declines during the "middle cut" collection. Depending on still type, the total "middle cut" spirit fraction can contain 50–70% alcohol. Extended collection of the spirit fraction will lower its alcohol content and increase the possibility of having "feints" in the spirit. As regards the volatility of congeners: acetaldehyde, diacetyl, methanol, and some sulfur compounds are congeners of high volatility; esters of various kinds are congeners with medium volatility; fusel oils (i.e., higher alcohols) such as propanol, isobutanol, furfural, and isoamylalcohol have lower volatility than many esters but are usually more volatile than fatty acid congeners such as propionic, isobutyric, isovaleric, hexanoic, and octanoic acids. Despite differences in volatility, all these congeners can be found in the spirit, at levels that characterize the spirit type. The duration of collection of fractions containing these compounds is crucial as regards the distinctiveness and quality expectations of the spirit product.

Still size, shape, and distillation volume also affect the composition and levels of congeners present in the "middle cut" (i.e., spirit). The insertion of a water-cooled "purifier" between the neck of the still and the condenser also acts to reduce congener levels and lightens the spirit. The single distillation of Cachaça into "foreshots," "middle cut," and "feints" in small pot stills with cooling worms makes the middle cut spirit of Cachaça a distinctly different product from rum which is double distilled or triple distilled. Rums tend to have lower levels of flavor congeners. In general, in many spirits the fusel oils are in high concentration but do not dominate the overall aroma and taste because they are counter-balanced by esters and aldehydes.

Esters confer fruity and floral aromas to spirits and although esters are lost in the "foreshots," the levels retained in the "middle cut" (the spirit) are vitally important. In this regard, butanol, propanol, and aldehydes play important parts in giving distinctiveness to different spirits but when these congeners are balanced with esters and other flavor compounds, a more complex spirit is achieved. Phenol, cresol, and guaicaol compounds are derived from peated malts. These substances are distilled into the spirit and confer medicinal, smokey, and phenolic aromas and taste to Scotch malt whisky. The intensities of these compounds are balanced by congeners such as esters.

Methanol is regarded as an undesirable compound in spirits but is produced in high quantities in non-cereal mashes of plant tissue (e.g., potato, agave and fruits, Table 2). This highly volatile compound is dangerous to health and is absent from most distilled spirits but is present in "safe levels" in Eau de vie. It is a very volatile compound and should be removed in "foreshots" but fruit mashes contain high levels of pectin from which significant quantities of methanol are derived during mashing (extraction). Preheating of fruits to destroy the enzymes that release methanol or the fermentation of fruit juices instead of mashed fruits significantly reduces the levels of methanol produced.

Properties of copper in distilling The patina, which forms on the internal surface of pot stills, can function to reduce the levels of off-flavor sulfur compounds i.e., sulfides (e.g., dimethyl sulfide and mercaptans) from the spirit. Although copper can be detected in some spirits, the levels are within safe food levels.

Distillation Using Continuous Stills

Continuous stills are large vertical constructions. They contain internal sheets of copper which perform the same function as the copper in pot stills. In the Coffey stills there are two columns, the analyzer and rectifier. The 6–8% ethanol ferment or mash is heated as it passes down the rectifier. This heated mass then passes to the analyzer where steam is blown through it. Ethanol and flavor congeners are driven off. These pass back into the bottom of the rectifier and are collected at their designated heights from the lower plates to the higher plates of the rectifying column. For example, plates may ascend from 1 to 39: plate 7 is rich in isoamyl alcohol (fusel oils), plate 14 is rich in isobutyl alcohol, plate 23 is rich in n-propyl alcohol, plate 32 is rich in ethanol at ~94%. Ethanol concentration increases from plate 1 to plate 32. Volatiles such as methanol, sulfur compounds, and acetaldehyde are found in plates 35–39. An alternative type of continuous still is the

column still. This comprises of a beer stripper where the 6–8% ethanol ferment is heated using stem, as in the analyzer. The vapors pass to the bottom of the concentrator which, like the rectifying column, fractionates the vaporized compounds at appropriate plates, for example: plate 5 (fusel oils, e.g., isoamylalcohol), plate 8 (propanol), plate 35 (ethanol, 95%), and the topmost plate 40 (methanol and volatile sulfur compounds). In all stills, condensers are connected to condense vapors that leave the still.

American whiskies are produced in continuous stills. They cannot be distilled above 80% ethanol and therefore contain more congeners than Scotch grain whisky at 94% ethanol and vodka and gin spirit at 96% ethanol. Canadian whiskies are produced from maize, rye, malted barley, and malted rye. Spirit fractions are collected between 65% and 95% ethanol and are used to produce different distilled products. Vodka and gin spirit (94% alcohol) may be passed through an extractive (water/steam) column still, which removes traces of volatiles such as methanol and diacetyl. The spirit is then concentrated in a rectifier where fusel oil is drawn off lower down the rectifier. The spirit is now at least 96% ethanol and is passed finally through a demethylizer to remove the last traces of methanol. In some plants, neutral spirit for vodka production is passed through charcoal to assist the purification process. During mashing, glycerol can be converted by lactic acid bacteria to acrolein which escapes during distillation causing an irritating pepper odor in the distillery.

Maturation

As indicated in Figure 5, distilled spirits are usually matured in wooden barrels for minimum periods of time. Some spirits are not matured such as vodka and gin, whereas, by law, Scotch whisky spirit and Irish and Canadian whiskey spirits are matured in oak casks for a minimum period of 3 years. American whiskies are matured for a minimum time of 2 years. The maturation periods for rums are variable – from, not at all (e.g., some light rums), to weeks or years, for heavy rums. Cachaça of the highest quality is matured in wooden barrels, especially oak and for at least 2 years. Brandies (e.g., cognac) are matured in oak barrels and, like Scotch whisky, can be matured for over 20 years. Maturation can take place in new, charred, wooden barrels (e.g., cognac or American bourbon whiskies) or in oak barrels previously used for sherry or bourbon. Port, madeira, and a variety of sherry barrels are now being used by some distillers to "finish" the maturation periods of their whiskies for wider brand appeal. Legally, tequila must be matured in oak casks for 2 months (rested tequila) or 1 year (aged tequila).

Different oak species are used for barrel construction, e.g., *Quercus ruber* (English), *Quercus petraea* (Spanish or French), or *Quercus alba* (USA). Barrel staves are sawn so that the normal tangential loss of water from the tree stem is avoided. Different spirits are filled into barrels at different strengths of ethanol. Spirit strengths of ~63.5% ethanol are most

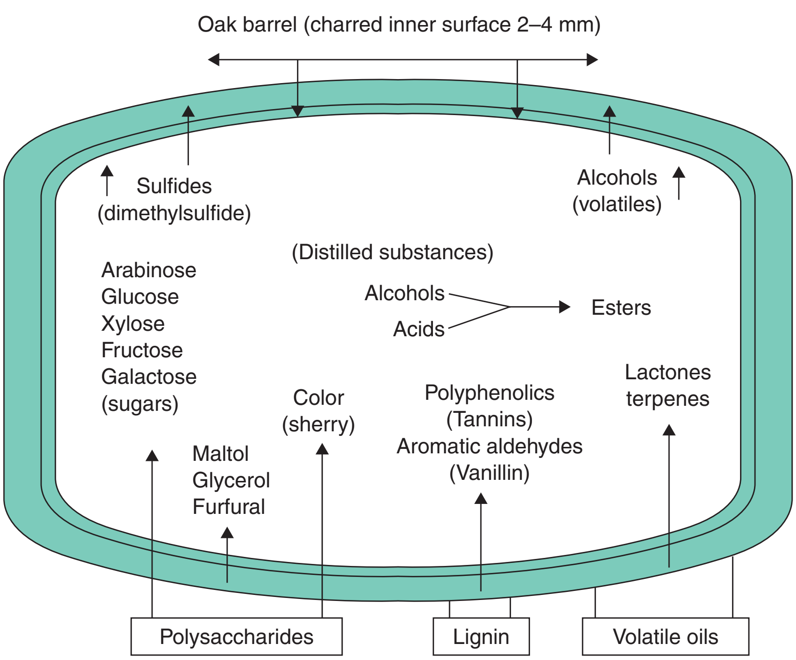

Figure 5 Maturation of distilled spirit ("middle cut") in oak barrels.

extractive. Temperature conditions influence maturation rate and maturation results. High temperature accelerates ethanol loss from barrels. For Scotch whisky, which can only be matured in oak casks, a loss of ~2% ("the angels' share") of the contents of the barrel occurs each year. In such maturation conditions, from an initial fill of 63.5% ethanol, ~58% ethanol will remain after a maturation period of 12 years. During maturation, unpleasant compounds are extracted by the barrel; pleasant compounds are released into the spirit and various important flavor compounds such as esters are formed in the spirit (Figure 5). The active charred inner surface of the barrel contains carbon which absorbs the unpleasant flavors of dimethylsulfide, dimethyldisulfide, methional, and methional acetate from the whisky, but not dimethyltrisulfide which, even at low concentrations of 4 ppb can be detected organoleptically (i.e., by taste or smell). From the scorched subsurface, important wood complexes are released into the spirit, adjusting its flavor, aroma, and increasing its color. Hydrolyzable tannins released into the spirit promote oxidative reactions such as ester formation between alcohols and acids.

Lignin is the strengthening material of wood and is a complex polymer which, when scorched by charring, releases aromatic aldehydes into the spirits such as vanillin and coniferaldehyde. Vanillins confer vanilla-like aromas to the spirit. Vanillin levels are very high in new barrels after charring and are characteristic flavors of bourbons and cognac. Other spirits that are matured in ex-bourbon casks also have detectable levels of vanilla-like aroma and taste. Low-level sweetness is conferred by the release of simple compounds such as glycerol and monosaccharide sugars such as xylose, arabinose, and glucose. Dry toasted malting flavors come from the release of furfural and maltol. American oak barrels release more lactones into the spirit than Spanish oak barrels. *Cis*-lactones confer desirable woody aromas and sweet, smooth, coconut flavors. Components of tannins such as gallic acid and ellagic acid can contribute astringency and can be oxidized to give color and fragrant compounds. The solid matter content of whisky increases by $\sim 2.5\,\mathrm{g\,l^{-1}}$ over a period of 12 years. Some of this material is lipid material (fatty acid esters) that will form hazes when water is added to matured spirit products, if such products are not cold filtered. Cask strength Scotch whiskies which are not filtered tend to form hazes when water is added. Metal ions can also form flocs, which are removed by filtration of the product. Pieces of charcoal that are dislodged from the charred surface of the barrel are also removed during filtration. The sherry flavors and vanilla flavors of distilled products are derived from the barrels in which they are matured. Sherry barrels also contribute color to maturing spirits.

Repeated use of a barrel will deplete its reservoir of color-producing materials and flavor compounds, and its ability to remove undesirable compounds such as sulfides. Such barrels are rejuvinated by scraping away the inner carbon surface and recharring the newly exposed wood. A barrel may last as long as forty years. However, its effectiveness declines over these years. Maturation moderates the volatility and increases the smoothness of the spirit. This is particularly important in high congener spirits.

Blending and Bottling

Before blending or vatting, the spirit is checked before the casks are emptied and collected in tanks. In general, whiskies, Cachaça, rums, brandies, or tequila are vatted and left to "marry" before being reduced with water of low mineral content to bottling strength. The ethanol levels of vodka and gin are also reduced using low mineral water. Judicious vatting (mixing) of cognac of different ethanol concentrations is effected to arrive at the bottling strength required. The mixing of generic spirits can be referred to as vatting. However, blending is used to describe the mixing of different kinds of spirits (e.g., malt and grain whiskies). In this regard, malt whiskies can be described as "pure" single malts (malt whisky from one distillery), "pure" malts (mixture (vatting) of different malt whiskies), or "blends" of malt and grain whiskies. Here, pure is taken to mean of one kind. The mixing of Cachaça products from different production operations is equivalent to the vatting of single malts because the Cachaça products used are different in character but are produced traditionally and are therefore of one kind. In contrast, in America, blended whiskies will contain grain whiskey, neutral spirit or light whiskey and a complement of heavy whiskey or whiskies such as bourbon or maize whiskey. These heavy whiskies are called "straights" if matured for more than 2 years. As in Ireland, the mash bill and still type determine the types of whiskies that are blended: such as products of high congener levels (malt or high malt whiskies) and products of low congener (high grain whiskies) levels. In Canada, light whiskies, made from rye and malted barley and malted rye, in continuous stills are blended with high flavor corn whiskies (65–80% ethanol), made from ~60% corn (maize), rye, and malted barley in either pot stills or continuous stills. Some Canadian whiskies are blended with wines, sherries, brandies, rums, bourbons, and malt whiskies to create different flavors and aromas. Lighter whiskies may be used in

larger quantities than heavier spirits; they may not only add lightness but also add flavor notes of freshness, which are crucial to the "drinkability" of blended whiskies.

Since blended whiskies, e.g., Scotch blends, can contain as many as 30–40 malt whiskies and ~6–8 grain whiskies, the overall complexity is greater than any comparable single malt. Blending extends product range and provides the possibility of arriving at new products which the public may prefer. This can take a long time; but the opportunity of developing new products should not be ignored. The levels of important congener compounds (e.g., esters) may not be reduced by blending because very highly flavored whiskies in the blend can compensate for reduction of esters by dilution with grain whiskies which have low congener levels. In this regard, some blended Scotch whiskies can have similar ester contents to malt whiskies, even though a malt whisky may have 4–5 times as many esters as a grain whisky. Blending is the high art of distilled beverage production, providing the customer with consistency and complexity without losing the high traditional qualities of a wide range of individual products which are blended together to extend drinkability.

Conclusion

Reference has not been made to the by-products of the distillation process. In some plants (e.g., Scotch grain whisky) carbon dioxide is collected and sold, spent grains from the mashing process and spent materials from the distillation process (stillage) are dried and sold as animal feed. Wastewater (backset) is kept hot (e.g., 65–95°C) and reused as part of the mashing-in liquor or part of the cooking liquor. This liquor contains lactic acid. It is acidic, nutritious, and is a contributing factor to the term "sour mash" in American whiskey production. In addition, fusel oils are collected during the production of grain whisky and sold to the perfume industry. Waste sugar cane skins and fiber (bagasse) are used as fuel. These practices show that the distilling process is "environment friendly" because most of the products of the process are recovered and sold. Copper in the stillage can be problematic in animal feed but this is primarily a problem for single gut animals. The use of caramel of the highest quality is permitted in the industry to adjust the color of spirit products to expected levels. In most cases, very small levels are used compared with the very high levels used in, for example, chocolates, cola, and gravy mixes. In general, distilled beverages are ethanol-based products which are made with sound science and high art and, from the levels of their sales worldwide, are not only pleasant to drink, they also play an important part in defining the culture from which they originate. Those who produce them are proud of their distinctiveness and quality. An example of such pride can be found in Robert Burns' poem, "John Barleycorn," which accurately describes the production of Scotch whisky and glorifies its virtues – virtues Burns described collectively as a "cup of kindness" in the universal New Year's song, "Auld Lang Syne." He believed passionately that whisky and "freedom" went together. Maybe the same beliefs could be extended to other spirit beverages that reflect historical custom and practice (culture).

In order to protect standards of production and cultural heritage, the essential features of production of distilled spirit beverages should be enshrined in the law, as is the case for many of the distilled beverages described in Tables 1 and 2. In this regard, original place of production, raw material used, production process employed and overall aroma and taste should be taken into consideration. The spirit industry has always encouraged moderate drinking because it is fully aware that excessive alcohol consumption can cause health and social problems. The value of moderate consumption of alcohol, as regards improved cardiovascular function, is still being researched but the results so far are encouraging. Although, the production of distilled spirit beverages sustains many jobs and creates high tax returns to various governments, their contribution to the culture of celebration is probably their most important merit in society.

BREADS

T R Moore, American Institute of Baking, Manhattan, KS, USA

Introduction

Bread, in one form or another, has served as mankind's Staff of Life for centuries. Its ability to provide sustenance to the human body is remarkable, as evidenced by analysis of its dietary components. While many people around the globe think of bread as simply a staple of the daily diet, it is much more than that to many others. To the wheat breeders, farmers, millers, and bakers of the world, bread is a means of providing for themselves and their families, a product to be proud of, and practically a way of life.

As would be expected of a product that has been in existence for so long, bread has evolved over the years such that it means different things to different people. Indeed, the geographical and cultural differences in the product known as "bread" are quite broad, as evidenced by the tremendous array of bread varieties available today in just the North American market. Pan breads, hearth breads, buns and rolls, and flat breads are increasingly available around the world, even if they are not indigenous to the consumer's homeland. Simply put, the differences between breads are largely a function of the ingredients used, and the manner in which these ingredients are processed into the final product.

Ingredients

Various ingredients are used in bread formulas to manipulate the characteristics of the finished product. As man has learned over time, only two ingredients are absolutely necessary to make a palatable loaf of bread, those being wheat flour and water. As time went by and man learned more about his surroundings, he discovered that salt and yeast added flavor and lightness to his bread. Today, additional ingredients are used in bread to meet the demands of the modern-day consumer, namely, better keeping qualities, better flavor, softer (or firmer) texture, and other physical and sensory improvements. As mentioned previously, geographical and cultural differences exist between breads, meaning that ingredients that are commonly used in North American, British, and Australian pan breads may not be used in German rye bread, French baguettes, or Arabic bread, for example. See Table 1 for common ingredients and their functionality.

Equipment

As detailed in **Bakeries**, the modern commercial bakery houses many pieces of specialized equipment. The goal of using modern automated equipment is to carry out the basic steps of the dough production process in bulk quantities, and to do it profitably. Equipment design, construction, and usage is truly global, with bakers all over the world buying and using equipment made in foreign countries. See Table 2 for an overview on equipment used for modern bread production.

Dough-Making Processes

Whether bread is made by hand or by machine, certain steps of the bread-making process are the same. Bread owes its uniqueness not only to the ingredients and equipment used in its manufacture, but also to the different processes by which dough is made. Most of these processes are of geographical or cultural origin, and are still practiced in the areas of their founding today. However, with globalization of trade and world travel, consumers now demand products that were not familiar to them in the past. It is not difficult to find authentic French bread in America, flour tortillas in Australia, or pita bread in Hong Kong. However, achieving the unique characteristics of different breads often requires that a specific dough-making process be used.

Table 1 Functions of bread ingredients

Ingredient	*Function(s)*
Wheat flour	Forms structure and provides body Contributes gluten-forming proteins Contributes starch for heat-induced formation of crumb
Water	Hydrates flour protein and damaged starch Acts as solvent for other ingredients Controls dough temperature Contributes pan flow Contributes to shelf life
Salt	Enhances flavor of product Strengthens gluten network Controls fermentation rate
Yeast	Provides leavening Metabolizes fermentable sugars into CO_2 and alcohol Fermentation products contribute to bread flavor
Sweeteners	Serve as food source for yeast Enhance flavor of product Contribute to crust coloration Act as product tenderizer Contribute to shelf life
Shortening	Lubricates dough system Facilitates easier expansion of gas cells in dough Tenderizes crust Facilitates easier slicing Contributes to shelf life
Dairy products	Contribute to nutrition profile of product Provide dough buffering Enhance flavor of product Contribute to crust coloration
Wheat gluten	Strengthens dough Increases water absorption Provides greater baked loaf volume
Yeast food	Enhances fermentation process Provides yeast nutrients Acts as water conditioner Conditions dough (with optional oxidant)
Enzymes	Extend shelf life (amylase) Convert starches into fermentable sugars (amylase) Shorten dough mixing time (protease) Strengthen dough (glucose oxidase, xylanase) Provide greater baked loaf volume (fungal amylase, xylanase)
Preservatives	Retard mold growth Contribute to shelf life

Straight Dough Process

As noted in Figure 1, this is an uncomplicated process whereby all the ingredients are loaded "straight" into the mixer. The dough is mixed, then allowed a bulk fermentation period of 60 min to 4 h, during which the dough is "punched down" to control expansion. After the fermentation period, the dough proceeds to "make up" a bakery term for the process of cutting and forming smaller dough pieces.

No-Time Straight Dough Process

This process is a variation of the straight dough method. It does away with the bulk fermentation period, substituting in its place chemical dough development, or the use of oxidizing agents and mix time reducers. A slightly modified version of this process is used for the manufacture of frozen dough products, which are used extensively by supermarket bakeries in North America, Europe, and elsewhere.

Sponge-Dough Process

This process is dominant in North America for the production of pan breads, and also finds use in other countries where pan breads are popular. The sponge is a thick stiff mass, "plastic" in texture, which contains most of the formula flour, water, and yeast. After mixing, the sponge is allowed to ferment for 3–4 h , and is then remixed with the remaining dough ingredients. A short rest period, or "floor time," is given to the finished dough before it proceeds to the makeup stage, as shown in Figure 2. Breads made in other parts of the world use a similar process, but the names are different. For example, Italian breads such as ciabatta and pugliese can be made with a biga, which is very similar to a North American sponge except for the longer fermentation time it is given. French breads, including baguettes and batards, can be made with poolish, a liquid version of the sponge that actually originated in Poland, or with levain, a slightly modified version of sourdough.

Liquid Sponge Process

This is a close relative of the sponge-dough process, but as the name implies, it is liquid in nature, containing at least as much water as flour. This enables the fermentation process to take place in stainless steel tanks, as shown in Figure 3, with the chilled liquid sponge pumped to the dough mixer, a great production advantage. The fermentation time is shorter for liquid sponges than for plastic sponges, usually on the order of 60 min to 3 h.

Continuous Mix Process

This process enjoyed great popularity in North American commercial bakeries in the 1960s and 1970s, particularly for sliced white pan bread. As the name implies, this process produced bread dough continuously, rather than in individual batches. Ingredients were metered into a high-speed developer head, which mixed the dough and

Table 2 Common wholesale bread bakery equipment

Equipment	*Purpose*	*Comments*
Dough mixer	Imparts mechanical shear to flour proteins and water to form gluten and develop dough mass	Capacity of up to 1400 kg. Can be horizontal or vertical. Mixer bowl can be refrigerated
Divider	"Divides" large dough mass into loaf-sized pieces	The bakery's "cash register"
Rounder	Forms divided dough piece into smooth, tight ball	Skin on exterior of dough ball helps to retain gas
Intermediate proofer	Relaxes rounded dough balls	Dough balls ride on trays pulled by moving chain
Sheeter moulder	Expels gas from and flattens dough balls with sheeting rollers, curls dough sheet into cylinder, and seals seam	Straight grain, cross grain, and curling molders all commonly used
Panner	Drops molded dough pieces into pans on conveyor below	Can index dough pieces into pans with seams on bottom
Proofer	Allows panned dough to rise to proper height prior to baking	Employs controlled temperature and humidity
Oven	Bakes dough, kills yeast, gelatinizes starch, and colors the crust	Tunnel, lap, rotary, deck, rack Steam required for hearth bread
Cooler	Cools baked loaves prior to slicing	Traveling tray, belt, spiral, rack
Slicer	Slices loaves prior to packaging	Band, reciprocating
Bagger	Pulls poly bag over sliced loaf	Bags closed with tie or clip

deposited it into baking pans. This process, while economical, eventually fell out of favor due to the lack of flavor and crumb strength in the bread. See Figure 4 for a schematic representation.

Chorleywood Bread Process

Developed by the British Baking Industries Research Association at Chorleywood, England, this process is used around the world to produce bread from lower protein flours. For this reason, it has not gained great acceptance in North America, where higher protein flours are the norm. It relies on a short time, intensive mixing, sometimes with partial vacuum in a Tweedy mixer, after which the developed dough is sent to the makeup stage, as depicted in Figure 5.

Sourdough Process

This is the oldest and most time consuming of the methods discussed, and is used to produce breads with rich and complex flavor and texture. More European in nature, sourdough breads are leavened with a sour "starter," which consists only of flour and water. The starter is allowed to ferment spontaneously, i.e., with only the naturally occurring microorganisms present in the flour (mainly wild yeast and lactic acid-producing bacteria). There is no added

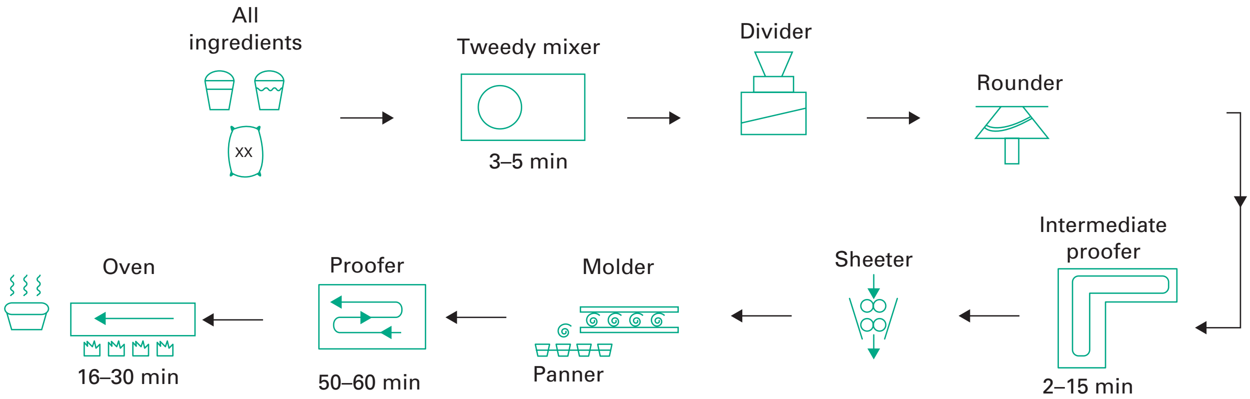

Figure 5 The Chorleywood process. (Adapted from *AIB Science of Baking Correspondence Course, module III Breads and Rolls* (2001) Dough Mixing and Development, pp. 7, 9. Manhattan, KS: American Institute of Baking.)

bakers' yeast. To keep the starter active for daily use, it must be fed, or replenished, periodically with added flour and water. Given proper feeding, a starter can last many years.

Bread Products

As previously discussed, bread can take many shapes and sizes, and can have extremely diverse sensory characteristics. In addition to the ingredients, equipment, and processes just mentioned, the various physical and organoleptic differences between bread products available today are attributable to cultural, geographical, and philosophical differences between the people who consume them. Generally, certain bread types are prevalent in certain cultures, and not in others. This is changing, however, with the world gradually becoming smaller with the advent of jet travel, wireless communication, and international trade.

Pan Breads

Loosely defined, these are simply breads that are baked in pans, either open or closed. These breads are very common in North America, Eastern and Western Europe, Australasia, and other industrialized areas of the world. Most of the pan bread baked on these continents is produced in large wholesale baking plants, using automated or semi-automated equipment. It is almost always sold presliced in polyethylene bread bags, and can be found in supermarkets, convenience stores, and other retail outlets.

In many of the aforementioned regions, pan breads are available as either "round-top" or "Pullman" loaves. Round-top bread is baked in a pan with an open top, so that the baked loaf has the characteristic round crown when viewed in profile (Figure 6). Pullman bread, commonly called "sandwich"

Figure 6 A round-top "strap" pan, background; sliced white bread, left; unsliced white bread, center; sliced cracked wheat bread, right.

bread, is baked in a rectangular pan, usually longer in length than a round-top pan, and has a lid placed over it after proofing and before baking (Figure 7). The lid prevents expansion of the dough in the oven, and results in a baked loaf having a nearly square profile. This bread is usually sliced slightly thinner than round-top bread for the North American market, the thought being most sandwich consumers want more of the filling per bite, and less of the bread.

Both round-top and Pullman loaves are available in several different varieties in most global markets. The most common include white bread, made with white refined wheat flour (Table 3), and wheat or "whole grain" bread, made with whole grain or whole meal wheat flour. In the USA, "whole-wheat" bread may be made only with 100% whole-wheat flour, while the more generic "wheat" bread may be made with a blend of white and whole-wheat flours (Table 4). These types of pan breads often need to be supplemented with dough strengtheners, as the inclusion

of significant amounts of whole-wheat flour weakens the gluten network and results in bread of lower baked volume. Other types of pan breads fall under the "variety" bread category – including multigrain bread, made with several cereal grains in whole-wheat dough; fiber bread made with varying types of high-fiber ingredients; and the ever-popular raisin bread (Figure 8). To respond to the consumer's desire for greater selection and to gain market share, bakers have developed pan breads that contain a wide array of specialty ingredients, including oats, crushed wheat, flaxseed, sunflower seeds, cinnamon, fruit, honey, and nuts. Additionally, toppings can be added to the surface of the proofed loaves prior to baking. Some of these include wheat bran, wheat flour, crushed wheat, sesame seed, flaxseed, sunflower seed, and other differentiating ingredients. A common practice for North American round-top breads is to split the surface of the proofed dough lengthwise with a water jet, and apply melted butter in the cavity, thus creating the "buttertop" variety (Figure 8).

Pan breads can be formulated to be lean, rich, or somewhere in between, depending on the consumer's taste. Most white breads tend to be soft and somewhat sweet, containing high amounts of water, shortening, and crumb softeners, along with higher sweetener levels. Wheat breads tend to be slightly dry, chewy, and not as sweet. Common in many markets around the globe is the practice of producing similar bread varieties at different price points, or perceived quality levels, for supermarket sale. Terms such as "value priced," "private label," "branded," "premium," and "superpremium" illustrate the practice. The differences are usually higher-quality ingredients, a richer formula, possibly the use of a pan with a slightly different shape, and more elaborate packaging graphics.

Hearth Breads

Historically, hearth breads, also referred to as artisan breads or rustic breads, have been made from relatively stiff and dry doughs so that they could be baked directly on the hearth, or floor, of the oven, without the benefit of a pan to impart shape or structure to the loaves. Today, the best-quality hearth breads are still made this way, especially by European bakers. While French and Italian bakers have traditionally lead their overseas counterparts in hearth bread quality, excellent product can increasingly be found in all corners of the world. In North America, this type of baking has enjoyed a true renaissance, with hundreds of small and medium-sized bakeries turning out French baguettes, batards, and boules, Vienna bread, and crusty hard rolls. Bakeries in Japan, Korea, Hong Kong, and Thailand offer their customers similar product, as do those in Ireland, Israel, and Argentina.

The best known of the hearth breads is generically referred to as French bread. However, the term does

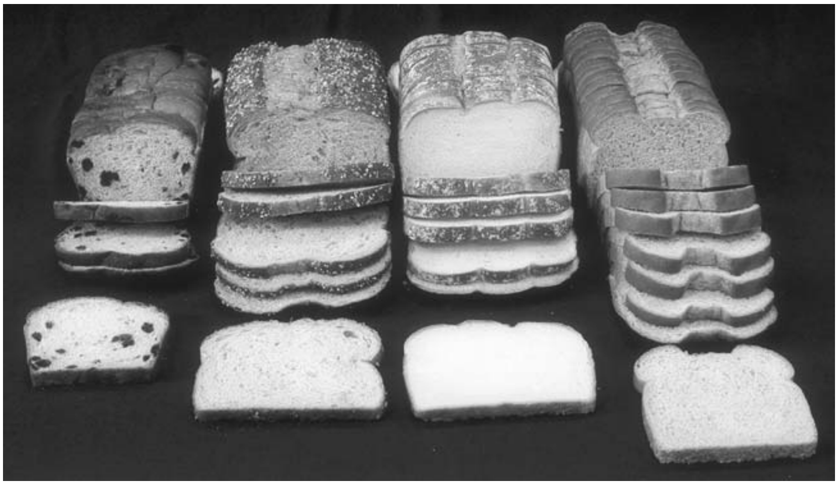

Figure 8 Left to right: raisin bread; split and topped seven-grain bread; double-split and topped fiber bread; buttertop wheat bread.

not do justice to the broad array of bread products produced in France. Indeed, the French take their bread so seriously that the government found it necessary to legally define *baguette*, and to regulate the various methods of bread making that are employed there. In France, French bread is made with wheat flour, salt, and water, with fermentation carried out by levain, direct addition of fresh yeast, or the addition of prefermented dough. In North America, certain compromises have been made to adapt French bread to the consumer's palate and to the producer's balance sheet. For example, shortening and a small amount of sweetener are sometimes added, to make the bread softer and sweeter tasting, and to extend the shelf life beyond the usual few hours (Table 5). Interestingly, the inclusion of these two ingredients in French bread is not legal in France.

True French bread, whether it is made in France or elsewhere, is available in several shapes and sizes. Baguette is the term for a long, narrow loaf with rounded ends, measuring 60–70 cm in length and weighing 250 g. It has seven characteristic slashes applied to the top surface after the proofing step, which helps control bursting during baking. A batard is similar to a baguette in weight, but measures only 35–40 cm in length and carries only three slashes. Ficelle is smaller still, weighing 125 g with a length of 40–45 cm. It usually has five surface slashes. Parisian is a large loaf weighing 400 g and measuring 60–70 cm in length. It has five to seven surface slashes. Boules are circular loaves, and can be of varying weights and diameters. Various surface designs are applied via slashing in order to give the boule a distinctive appearance (Figure 9). The crust of these breads should be relatively thin, crispy, and blister free, courtesy of the steam present in the oven chamber during baking.

Figure 9 French-style stick loaves and boule.

Crust color can vary from pale brown to practically black, depending on the region and consumer taste.

Internal characteristics are just as unique as the external appearance. The crumb color is usually creamy to pale yellow, with a very open and irregularly shaped grain structure. There are normally several moderately sized holes in each slice, giving the

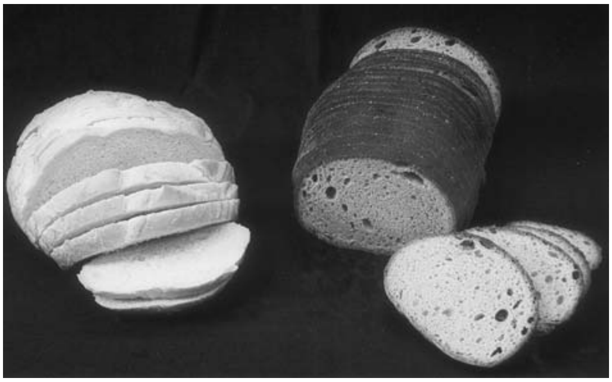

Figure 10 San Francisco sourdough boule, left; European sour rye bread, right.

crumb surface a rough texture. The crumb will be slightly chewy in the mouth.

Several different processes can be used to produce French bread, including the previously mentioned straight dough, sponge-dough, and sourdough processes.

In the USA, a close relative of French bread originated in the San Francisco, California region during the Gold Rush period of the late 1840s and early 1850s. Called San Francisco sourdough bread, it was a mainstay of the diets of gold miners. Today, it is still a fairly unique product in the American marketplace, in that it has a very characteristic sour flavor, open grain, and substantial crust (Figure 10). Many specialty sourdough bakeries have opened across the USA to capitalize on the growing consumer demand for this product. As the name indicates, the bread is made with a sour starter, also called a mother sponge (Table 6).

Table 6 Sourdough bread

Starter	11.4	Starter	25.0–34.0
		Salt	2.7
		Yeast, compressed[a]	0.17

[a] Optional.

Another type of hearth bread is rye bread, which takes its name from the inclusion of flour from the cereal grain rye. Rye bread has been produced around the world for centuries, and has gained great popularity for its distinctive flavor and dense, chewy crumb. In northern and eastern Europe, rye bread is a highlight of the meal, rather than an accompaniment. The types of rye bread are many, including American rye, Jewish rye, German rye, Russian rye, and Swedish rye, to name a few (Figure 10). The differences are largely due to the ingredients and consumer taste indigenous to the producing region.

Rye flour differs greatly from wheat flour in that its protein does not form gluten. As such, it contributes nothing to the strength of the dough or the volume of the bread. Therefore, the amount of rye flour that can be used in rye bread dough is limited, with the majority being wheat flour. Rye flour is available as light rye, medium rye, and dark rye; rye meal, rye flakes, and cracked rye are also available. Generally, rye breads are differentiated based on the amount of wheat flour used and the type of rye flour that is chosen (Table 7). This creates rye breads having different crumb color, crumb density, and flavor. In some types, it is common practice to include ground or whole caraway seed in the formula to further accentuate the flavor of the bread.

Table 7 Sponge and dough rye bread

Ingredient	*American (light)*	*Swedish*	*Jewish*

Caraway seed	1.0		
Syrup		12.0	
Nonfat milk solids		4.0	

[a] Wheat flour + rye flour(s) = 100%.

Rye bread is generally made with the sponge-dough process. Traditional pumpernickel bread, a dark and heavy version of rye bread, uses a sour made of whole rye meal. German sour rye bread is also produced with a sour.

Buns and Rolls

These are simply small individual units of baked bread, normally eaten with a meal or as the bread component of a sandwich. In North America, buns

are usually sweeter and richer in formulation (Table 8), while rolls tend to be made from leaner formulas (Table 5). Both products can be panned and baked either as single units or in clusters, depending on the intended users' desires. Buns and rolls can be made from the same types of dough as used for bread loaves. White, wheat, rye, and sourdough buns and rolls are common. The most popular usage of buns is for the ubiquitous hamburger and hot dog, as their respective buns are shaped and sliced specifically to accommodate those specialty meat items (Figure 11). Hamburger and hot dog buns are most usually made in wholesale bakeries on automated high-speed equipment in large quantities. Kaiser rolls, made from a lean bread dough formula (Figure 11), are also popular in North America. The dough pieces are flattened slightly after forming, then have a characteristic "star" pattern stamped into the top surface. The proofed rolls are baked with steam in the baking chamber to form the light, slightly crispy crust that is expected of the product.

As opposed to the North American taste, European rolls are traditionally of the hard type, made with lean formula dough and baked with steam in the oven to facilitate the formation of a crispy crust (Figure 12). Hard rolls are also available in other areas of the

Table 8 Sponge and dough hamburger and hot dog buns

Figure 12 Assorted hard rolls surrounded by croissants.

world, and are of good quality as long as two things are present in their manufacture – strong protein flour and oven steam.

Other types of rolls include croissants and brioche, both of European origin and very popular all over the world. The croissant (Figure 12) is made with laminated Danish pastry-type dough, i.e., the dough is actually comprised of many individual layers of dough and fat, usually unsalted butter. The dough is continually reduced in thickness through a series of sheeting steps, after each of which it is folded and sheeted again. This procedure is repeated until the proper number of laminations has been made. It is common for croissant dough to have anywhere from 36 to 72 dough/fat layers. These layers serve to trap moisture and carbon dioxide produced during fermentation. On exposure to oven heat, the moisture turns to steam which, in conjunction with the carbon dioxide gas, causes the croissant dough to "bloom" in the oven. This blooming action results in the formation of the light and flaky texture for which croissants are known.

Brioche is a light, sweet, yeasted roll that is made from a rich formula high in eggs, sugar, milk, and butter. As such, it finds favor as a dessert item, and is popular for holiday celebrations. It is usually made with the sponge-dough process, but can also be made with either the straight dough or sourdough methods. As the term "brioche" can apply just as easily to the dough as to the individual baked product, the rolls can take on many different shapes and sizes. In Europe, the appearance of brioche is often based on the regional preference of the baker and his clientele.

Flat Breads

These are the most widely consumed of all bread types, eaten daily by hundreds of millions of people all over the globe. While this number may seem questionably large at first, it is put into proper perspective by considering the wide selection of products available, many of which are not known or available to those outside of certain regions. Generally, flat breads can be divided into the single-layered and double-layered types.

Single-layered flat breads are consumed universally. For most North and Central Americans, the flat bread of choice is the tortilla. Indeed, for many people it is the bread accompaniment at most every meal. While the corn tortilla is the more traditional product, wheat flour tortillas have gained great acceptance in the USA and Canada, especially for the fast food trade (Figure 13). See Tables 9 and 10 for representative formulas. In many non-Hispanic homes in the USA, tortillas have become as common as sliced white pan bread. See **Tortillas** for additional information on tortillas.

Tanoor bread is another single-layered flat bread that is widely consumed, especially in parts of the

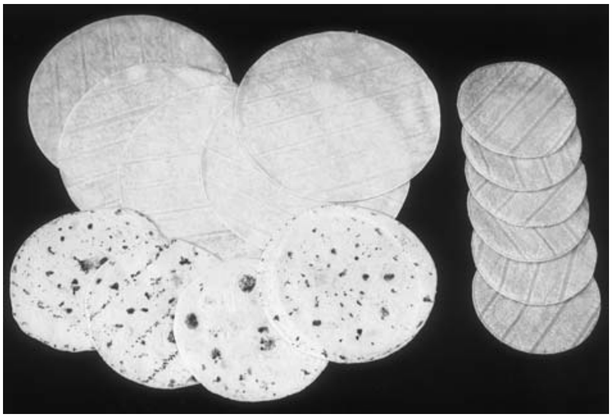

Figure 13 Large and small wheat flour tortillas, left; corn tortillas, right.

[b] Monocalcium phosphate, sorbic acid, citric acid, fumaric acid, calcium propionate, potassium sorbate, etc.

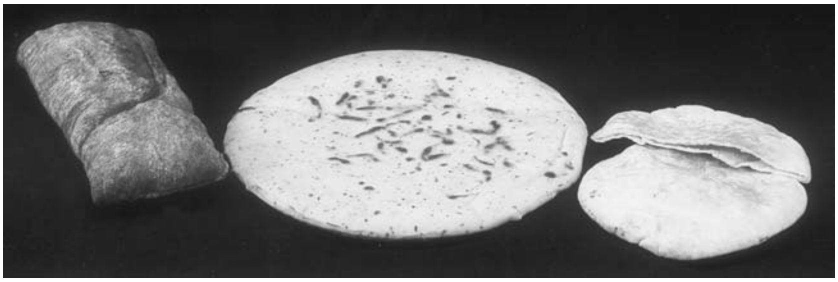

Figure 14 Ciabatta, left; focaccia, center; pita bread, right.

Middle East, India, and Pakistan. While it may be given slightly different names in different regions (taftoon in Iran, tanouri in Afghanistan), it is essentially the same product, with similar ingredients and processes used. It is made of wheat flour, soda (sodium bicarbonate), yeast, and water, with optional ingredients being salt and date syrup in certain types. Sourdough can be used in place of the yeast. It is baked into thin, oblong shapes.

Ciabatta is Italian in origin, and has gained a large following in Europe and North America (Figure 14). It is baked from lean formula sponge dough, usually consisting of wheat flour, water, yeast, and salt. Olive oil is sometimes added, especially in Italy. High amounts of water are added to the dough to give the baked bread its characteristic open and irregular crumb structure.

Similar to ciabatta, focaccia (Figure 14) uses the same basic ingredients but is prepared with the straight dough procedure, often with a long bulk fermentation period for added flavor. The dough is traditionally flattened in a shallow pan with the fingertips, then topped with various items such as onions, peppers, tomatoes, and seasonings. A short proof is given after which the dough is baked. Topped focaccia is seen as an upscale type of pizza in North America, and is a very popular item in boutique bakeries and cafes.

Pizza is a universally popular type of flat bread enjoyed all over the world. While pizza is usually distinguished by the toppings applied to it, the crust itself is subject to variation in thickness, texture, and added flavorings, depending on the particular geographical region in which it is served. Thickness can range from very thin and cracker like (0.5 cm) to thick and hearty (upwards of 5 cm). Crust texture is manipulated by the ingredients chosen, including flour strength, and the process used to manufacture the dough. Toppings vary widely, and are limited only by the imagination. Traditional US toppings include tomato sauce, mozzarella cheese, olive oil, and various herbs, vegetables, and meats.

Table 11 Straight dough arabic (Pita) bread

Ingredient	%
Flour[a]	100.0
Yeast (active dry)	0.5
Salt	1.5
Water	50.0

[a] All ingredients are given in bakers % (flour = 100%).

Chapati, also known as roti, is estimated to be the most widely consumed flat bread in the world. The people of Tibet, India, Pakistan, Afghanistan, and other countries eat it as their daily bread. It is unleavened, round in shape, and made with whole-wheat flour and water.

The most recognizable double-layered flat bread is Arabic bread, also known as pita bread (Table 11). This product is lean in formulation, round in shape, and has a characteristic "pocket" inside that defines the product (Figure 14). This pocket is formed largely by a second proofing step that is not given to single-layered flat breads. The second proof allows the formed dough surface to dry slightly. The resultant dough skin allows the product to balloon during baking, forming the internal pocket. Baking is carried out at high temperatures, normally 400°C, for short periods of time, usually 90–100 s. The combination of high temperature and short time helps to emphasize pocket formation by quickly converting internal dough moisture to steam, which, along with residual CO_2, accentuates the separation between the top and bottom of the bread.

Future Considerations

As it has with most things, technology will continue to affect the baking industry. Further advances in ingredients, equipment design, product shelf life, and distribution techniques will almost certainly give the bread baker advantages his ancestors never had. Implementing this technology to create wholesome and

appetizing breads that are also safe and profitable will prove advantageous for bakers and consumers alike.

BUCKWHEAT

Y Z Cai and H Corke, The University of Hong Kong, Hong Kong, People's Republic of China
W D Li, Shanxi University, Taiyuan, People's Republic of China

Introduction

Buckwheat originates in China and is widely cultivated as a minor crop in many places of the world. It is a pseudocereal crop, belonging to the genus *Fagopyrum* of the family Polygonaceae. There are two cultivated species, i.e., common buckwheat (*Fagopyrum esculentum*) and tartary buckwheat (*Fagopyrum tataricum*). Common buckwheat is most widely cultivated and utilized, while tartary buckwheat is mainly grown and consumed in China. The major buckwheat-producing and -consuming countries include China, Japan, Korea, Nepal, India, Russia, Ukraine, Poland, Hungary, Slovenia, Italy, Canada, Brazil, and the United States. Buckwheat is mostly consumed in the form of groats and flour, which are used as material for porridge, noodles, bread, pancakes, spaghetti, and other food items. Many traditional buckwheat foods are still popular in some countries, such as Japanese "soba" and "wantuo" and "helao" in China. Buckwheat is rich in protein of excellent quality as well as starch with special and different properties from other cereals. In addition, it also contains high levels of fiber, minerals, vitamins, and flavonoids with positive therapeutic effects on the human body. Buckwheat has increasingly attracted attention because of its positive effects on some chronic disease conditions, such as hypertension, hypercholesterolemia, diabetes, and other cardiovascular diseases. Buckwheat has further potential for use as an important functional food source.

General Aspects of Buckwheat Production

Buckwheat grows mainly in the northern hemisphere, notably in Russia, China, Japan, India, Poland, Ukraine, Canada, and USA. Buckwheat is also planted in the southern hemisphere, e.g., in Brazil, Australia, and South Africa. In 1993, Russia was the biggest producer of buckwheat in the world, with a planting area of more than 4 million hectares (Mha), mainly in the eastern and north eastern parts of the country. It is reported that in 1990, buckwheat yield per hectare reached 3400 kg in Russia. China has the longest history (since the seventh century AD) of buckwheat cultivation, and now ranks second in world production with an average annual cultivation area of ~1.33 Mha, and production fluctuating in the range of 0.5–0.9 million tons (Mt). Average yield per hectare is 527 kg for common buckwheat and 1294 kg for tartary buckwheat in 1986. In China, major production areas are in Inner Mongolia, Shanxi, Gansu, Shaanxi, Sichuan, Yunan, and Guizhou. Buckwheat is also cultivated to support the production of honey, and is considered one of the highest yielding honey plants.

Biological Aspects of Buckwheat

Buckwheat, a dicotyledonous plant, belongs to the genus *Fagopyrum* of the family Polygonaceae. *Fagopyrum* has 15 species, including two groups: (1) annual species: *F. esculentum* Moench (common buckwheat), *F. tataricum* L. (tartary or bitter buckwheat), *Fagopyrum giganteum* Krotov, etc.; (2) perennial species: *Fagopyrum cymosum* Meissn, *Fagopyrum suffruticosum* Fr. Schmidt, etc. Among these species, only *F. esculentum* and *F. tataricum* are cultivated species while others are wild species. Buckwheat has broad ecological adaptability and can grow well in adverse soil and climatic conditions; in particular, tartary buckwheat can grow in poor soils even at low temperature and low precipitation, such as in high altitude mountainous regions.

Common buckwheat is characterized by petiolate leaves, terminal and axillary flowers, and with corymbose or paniculate cyme. Tartary buckwheat has narrow-shaped leaves, more branches, and smaller flowers than common buckwheat, with inconspicuous greenish-white sepals. Buckwheat flowers are indefinite inflorescences that are white, pink, or yellow. Buckwheat grain is actually a fruit (achene) whose color ranges from a glossy or dull gray to brown or black. Buckwheat grain (achene) consists of hull (pericarp) and kernel, or seed (testa, aleurone layer, embryo, and endosperm). Such achenes are mostly triangular, ~4–9 mm long with 1000-grain weight ranging from 15 to 35 g. Common buckwheat grain is generally bigger and huskier than tartary buckwheat grain. Common buckwheat has a softer hull

than tartary buckwheat. Common buckwheat grain tastes harsh, and tartary buckwheat tastes slightly bitter.

Chemical Composition of Buckwheat

Chemical components of buckwheat include protein/amino acids, starch, lipids, fiber, minerals, vitamins, and other functional components (e.g., flavonoids, phytosterols, and fagopyrins). These are distributed in different parts of the buckwheat grain, e.g., protein mainly occurs in the aleurone layer and embryo, starch in the endosperm, and fiber, ash, and flavonoids are normally in testa and pericarp. Milling procedures, fineness, and flour yield influence chemical composition in the final products of buckwheat milling (Table 1). Different buckwheat varieties (genotypes) and plant conditions (soil and climate) also cause compositional differences.

Protein and Amino Acids

Buckwheat grain contains not only a high level of protein but also a good quality or nutritional balance of protein. Protein content of buckwheat grain and flour is similar to or slightly higher than that in wheat grain and flour (Table 1), but significantly higher than those in many other cereals (e.g., rice, maize, sorghum etc.). Amino acid composition of buckwheat protein is nutritionally well balanced, and is rich in essential types (e.g., lysine and arginine), compared with most cereals. Table 2 shows that all amino acids in buckwheat grain are higher than in wheat grain, except for glutamic acid and proline.

[b] Essential amino acids.

Carbohydrate

Carbohydrate (mainly starch) is the major component (59–74%) of buckwheat grain (Table 1). Amylose content in starch generally ranges from 20% to 26%. Starch granules are 2–15 μm in diameter, round, oval, or polygonal in shape with a few holes and pits on the surface. Buckwheat starch exhibits a typical A-type X-ray diffraction pattern and the crystallinity varies from 38.3% to 51.3%. Buckwheat grains also contain 0.65–0.76% reducing sugars, 0.79–1.16% oligosaccharides, and 0.1–0.2% non-starchy polysaccharides.

Lipids

Buckwheat grain contains 2.0–2.6% oil. Major fatty acids are palmitic (16:0), oleic (18:1), and linoleic (18:2) acids, with average values of 14.8%, 36.5%, and 35.5%, respectively. Unsaturated fatty acids constitute ~75–80% of total fatty acids.

Fiber

Buckwheat grain contains 9.3–10.9% crude fiber, ~20–30% of which is soluble dietary fiber. Common buckwheat grain generally has higher crude fiber than tartary buckwheat. Content of crude fiber in buckwheat flour commonly depends on the milling process because fiber is mainly distributed in testa and pericarp. Crude flour contains more fiber (3.4–6.9%) than fine flour (0.1–1.6%).

Minerals

Buckwheat grain is rich in Mg, Se, Fe, K, Ca, Cu, Mn, Zn, etc. Some studies show that buckwheat flour contains more Mg (11–13 times), Sr (5–36 times), Li (5–7 times), Fe (3–4 times), and K (2.9–3.6 times) than wheat flour. Additionally, a high level of Se is detected in tartary buckwheat flour (0.43 mg per kg).

Vitamins

Buckwheat grain contains higher levels of vitamin B_1 (thiamin), B_2 (riboflavin), E (tocopherol), and PP (nicotinic acid/amide) than most cereals (Table 3). Generally, tartary buckwheat has more vitamin B_1, B_2, and PP, but less vitamin E than common buckwheat.

Table 3 Comparison of vitamin contents between buckwheat flour and some cereal flour[a]

Vitamin[b]	*Buckwheat*	*Wheat*	*Rice*	*Maize*	*Oat*	*Sorghum*
Vitamin B_1	0.38	0.19	0.21		0.29	0.27

[b] mg per 100 g dwb (dry weight basis).
[c] Mean of 565 common buckwheat genotypes.
[d] Mean of 491 tartary buckwheat genotypes.

Therapeutic Components

Buckwheat is also rich in components with therapeutic effects, including flavonoids, phytosterols, fagopyrins, and cinnamic acid.

1. Flavonoids: Several flavonoids have been identified in tartary and common buckwheat, i.e., rutin, quercetin, quercitin, kaemferol, orientin/isoorientin, and vitexin/isovitexin. Rutin, also called vitamin P, is the major and most important flavonoid component in buckwheat, which is not found in cereals. All parts of the buckwheat plant (seeds, hulls, leaves, stems, flowers, and even roots) contain flavonoids. The flavonoid components and content in buckwheat differ among growth periods and among species and genotypes. Generally, the flavonoids in tartary buckwheat are significantly higher than that in common buckwheat. It is reported that common buckwheat grain contains 4–13 mg per g flavonoids, whereas tartary buckwheat grain has ~40 mg per g. In tartary buckwheat flowers, leaves, and stems, total flavonoid content reaches over 100 mg per g.
2. Phytosterols: Buckwheat contains several kinds of phytosterols, e.g., β-sitosterol, campesterol, stigmasterol, and isofucosterol. β-Sitosterol is the major sterol component, accounting for ~70% of total sterol content. Some studies report that de-hulled buckwheat groats after lipid extraction have 667–753 mg per kg β-sitosterol, 89–97 mg per kg campesterol, and a trace of stigmasterol. Phytosterols also occur in buckwheat pollen.
3. Fagopyrins: Fagopyrins normally occur in buckwheat grain in low quantity and are difficult to separate. The research projects in the field of fagopyrin isolation and development are still underway.
4. Cinnamic acid: Tartary buckwheat contains 2,4-dihydroxy-*cis*-cinnamic acid, which can be helpful for inhibiting black pigment formation on skin and preventing old age skin specks and freckles.

Antinutritional Inhibitors

Antinutritional factors have been found in buckwheat grain, such as trypsin inhibitors (I, II, and III) and

tannin. They may influence digestibility of buckwheat protein. Also, a high level of fiber in buckwheat may be considered as an antinutritional factor.

Nutritional Value and Properties of Major Components

Protein

Buckwheat is one of the best sources of high biological value protein in the plant kingdom. The biological value (BV) of buckwheat protein is 93, compared to egg albumin (100), soybean protein (68), and wheat protein (63). The high BV of buckwheat protein results in much higher utilizable protein value (20–30%) compared to other cereals, although its digestibility is relatively lower. Buckwheat protein complements other food proteins to improve the dietary amino acid balance. In buckwheat protein, threonine and methionine are the first and the second limiting amino acids, respectively, but they are quite abundant in other plant proteins.

In buckwheat grain, protein albumin is the major fraction (28–42%), and glutelin (11–21%) and globulin (14–20%) are next, whereas prolamin is the minor fraction (1.7–2.3%). Comparatively, wheat grain is high in prolamin and glutelin (70–75%). These differences between buckwheat and wheat lead to differences in food functional properties and processing quality. Because of the very low level of prolamin in buckwheat (i.e., free from gluten) and based on chemical and immunological studies, buckwheat protein is a valuable source of dietary protein for gluten-sensitive individuals and can be used for patients with gluten sensitivity (celiac disease).

Interesting findings on thiamin-binding protein (TBP) in buckwheat grain were reported in 1986. TBP can stabilize thiamin during storage through forming a complex between protein and thiamin, ordinarily at a 1 : 1 binding stoichiometry. After complexing, it can be digested by proteases and release the thiamin. Therefore, TBP can be used for patients who suffer from lack of thiamin and cannot store thiamin.

Studies at the University of Hong Kong found that buckwheat protein exhibited much higher solubility, better emulsifying activity, and slightly lower foaming ability, compared to soy protein, and poorer foaming ability than amaranth protein (Table 4). Recent Japanese studies indicated that the physico-chemical properties of buckwheat protein were obviously different from those of soy protein and casein. Buckwheat protein affected the rheological properties of maize starch. An increase in the peak viscosity due to the addition of buckwheat protein concentrate was observed, but a lesser increase from the addition of buckwheat protein hydrolysates. From the established relationship between pasting viscosity and granule swelling during gelatinization, it was concluded that the observations were due to the protein exerting a stabilizing factor on starch granule integrity. It was also observed that buckwheat protein addition weakened starch gel structure. This phenomenon was most likely due to the preferential interactions between starch granules and proteins during gelatinization and retrogradation.

Table 4 Functional properties of common buckwheat protein concentrates, compared to other protein isolates

Protein concentrate	*Emulsifying activity at pH 7.0 (%)*	*Solubility (%)*	*Foam stability (ml)*
Buckwheat	63.8	64.2	14
Soybean	50.6	33.3	20
Amaranth[a]	73.3	56.5	56

[a] From *A. cruentus* genotype (K350).

Furthermore, buckwheat protein concentrate was examined for direct utilization in an emulsion-type meat product comprising lean beef, pork fat, salt, and water. It was found that the use of buckwheat protein concentrate considerably affected both the emulsion and the cooked meat gel properties. Buckwheat protein showed favorable effects to be suitable as a meat extender, as good as soy protein. Also, buckwheat protein concentrate was tested for direct application in other food systems (wheat dough and noodles). Addition of the buckwheat protein concentrate could improve the mixing properties of wheat flour and produce a positive influence on noodle formulation and final product quality.

However, some reports pointed out a problem of the low digestibility of buckwheat protein, which might result from antinutritional factors: trypsin inhibitors, tannin, and a high content of dietary fiber. Buckwheat trypsin inhibitors are relatively thermo stable, acid resistant, and partially susceptible to pepsin action. In addition, allergens in buckwheat proteins have attracted attention. During buckwheat grain milling and food processing, some workers have allergic reactions, such as nose itching, sneezing, rhinorrhea, dyspnea, asthma, and even more serious symptoms. It is necessary to know more about the behavior and processing properties of specific buckwheat allergenic proteins.

Starch

Some reports suggested that buckwheat starch normally has higher peak viscosity, higher gelatinization

temperature, greater swelling power, and higher susceptibility to acid and enzymatic degradation when compared with cereal starches (maize and wheat). Some studies indicated that buckwheat starch retrogradation is generally slower than that of maize and wheat starch. Buckwheat starch has lower syneresis when stored at 4°C for 3–10 days and has better stability to syneresis after freeze-thaw cycles at −12°C–25°C.

The authors investigated the starch properties of common and tartary buckwheat compared to wheat starch. Clear differences were found in physico-chemical properties between buckwheat and wheat, but less variation was observed between three common and three tartary buckwheat genotypes. Buckwheat starch had higher peak gelatinization temperature (average $T_p = 68.7°C$) than standard wheat starch ($T_p = 63.7°C$). The important pasting properties of buckwheat starch were higher hot paste viscosity and cool paste viscosity, better resistance to shear thinning, and less effect of NaCl on peak viscosity than for wheat starch. Starch swelling volume is 27.4–28.0 ml for common buckwheat and 26.5–30.8 ml for tartary buckwheat, compared to the reference (20.1 ml) for wheat starch.

Investigations on the nutritional properties of buckwheat starch showed that it has potential use in the design of foods with lower glycemic index properties. The *in vitro* rate of starch hydrolysis and resistant-starch formation in boiled buckwheat groats and in a series of buckwheat-wheat breads and noodles (30–70% buckwheat flour) were evaluated. The highest level of resistant starch (6% total starch basis) and the lowest starch hydrolysis index was found in boiled buckwheat groats. The rate of *in vitro* amylolysis was much lower in all buckwheat products compared to the reference whole wheat bread or noodles. Consumption of boiled buckwheat groats or bread and noodles containing more buckwheat induced significantly lower postprandial blood glucose and insulin responses than with whole wheat bread.

Additionally, several researchers reported the effects of processing treatments (steaming or autoclaving, extruding, etc.) on buckwheat starch properties. The results showed that hydrothermal treatment increases gelatinization temperature, swelling power, and solubility of buckwheat starch. Autoclaving/cooling treatment of buckwheat groats resulted in improved availability of buckwheat starch and led to more apparent amylose and true amylose in the buckwheat starch and more resistant-starch formation in comparison to the untreated samples. It was also reported that extrusion influenced the physicochemical properties of starch and formation of starch–protein and starch–lipid complexes in extruded mixtures containing buckwheat flour and starch. Starch–protein complexes formed during extrusion played an important role in the stability of the porous structure in the extruded products containing buckwheat starch.

Therapeutic Effects of Buckwheat

Buckwheat, especially tartary buckwheat, has been regarded as an effective medicinal herb in Chinese medicine for more than 1000 years. Over 80 prescriptions utilizing buckwheat in the treatment of many diseases have been described in Chinese traditional medicine books. In modern times, buckwheat products are popular as functional or therapeutic foods in China and some other countries. Regular consumption of buckwheat foods may reduce the occurrence of hyperlipidemia, obesity, and diabetes. A clinical trial in Beijing Tongren Hospital showed that tartary buckwheat flour had hypolipidemic and hypoglycemic effective in treating hyperlipidemia and diabetes (Table 5). Table 6 shows that health foods made from tartary buckwheat have positive effects in reducing cholesterol, blood lipid, blood sugar, urinary sugar, and other indices. These therapeutic effects should be attributed to unique proteins, resistant starch, and dietary fiber as well as vitamins, minerals, flavonoids, and phytosterols in buckwheat.

Some studies suggest that protein and indigestible carbohydrates (fiber and resistant starch) of buckwheat can be used as potential functional food additives to treat hypertension, obesity, constipation, etc. Buckwheat protein extract could lower blood cholesterol level more efficiently, compared with

Table 5 Clinical effects of tartary buckwheat flour on hyperlipidemia and diabetes (hyperglycemia) after one-month dietary treatment[a]

Testing index[b]	*Before treatment*	*After treatment*
Hypolipidemic effect		
Serum triglyceride (mg dl^{-1}) ($n = 18$)	310 ± 241	233 ± 173
Serum cholesterol (mg dl^{-1}) ($n = 13$)	247 ± 57	197 ± 43
Hypoglycemic effect		
Blood sugar (mg dl^{-1}) ($n = 23$)	202 ± 46	157 ± 40
Urinary sugar (g 24 h^{-1}) ($n = 27$)	44 ± 43	20 ± 22

Beijing: Agricultural Publishing House and Corke H and Lin RF (eds.) (1998) *Proceedings of the 1st International Conference on Asian Food Product Development – Focus on Specialty Grains and Grain Products* (6–10 September, 1998, Taiyuan, China). Beijing and New York: Science Press.
[b] *n* is number of subjects.

soy protein and casein. Sulfur-containing amino acids and glycine as well as arginine and lysine are also considered to have important influence on this cholesterol-lowering effect. These amino acids can conduct down-regulation of hepatic LDL receptors and improve the removal of cholesterol and its esters in outlying tissues and thus reduce the serum cholesterol level. Recent studies have further indicated that consumption of buckwheat protein can cause suppression in body fat, constipation, mammary carcinogenesis, and colon carcinogensis in rats and in the formation of cholesterol gallstones in hamsters. Some researchers explain that the cholesterol-lowering, obesity-treating, and diabetes-controlling effects are also possibly associated with other components (dietary fiber and resistant starch) in buckwheat. The metabolites, formed during fermentation of resistant starch and other indigestible carbohydrates in the large intestine, contribute to the maintenance of colon health and also have beneficial effects on glucose metabolism.

The flavonoids from buckwheat (especially tartary buckwheat) have been found to be effective in reducing blood cholesterol levels, keeping capillaries and arteries strong and flexible, improving blood microcirculation, and protecting blood vessels from rupturing and forming clots. These flavonoids also demonstrate antioxidant, antimicrobial, and anti-inflammatory activity. Because tartary buckwheat leaves and stems contain high concentrations of rutin and other flavonoids at flowering, extracts of buckwheat plants are helpful for treating keratitis, while dried powdered buckwheat plants are sometimes used for curing external wounds and ulcers.

The vitamins and minerals (Mg, Fe, Se, etc.) in buckwheat can also play a crucial complementary role in the above therapeutic effects. Phytosterols found in buckwheat grain, although at a low level, also showed positive effects on blood cholesterol level. Other functions of buckwheat sterols are waiting for further investigation, because some phytosterols from other plant sources were found to have strong pharmaceutical effects, e.g., antivirus and antitumor activity. Also, there is a report that the fagopyrins isolated in buckwheat grain are an effective component for the treatment of type II diabetes. However, there is still some dispute on this issue.

Buckwheat Food Products

Buckwheat products are recognized as functional food in some Asian countries. Buckwheat, as a nutritional staple crop and medicinal herb for Chinese consumption, has been widely grown for a long time. A rich array of traditional buckwheat foods are found in various places of China, such as buckwheat wantuo and helao (or hele), buckwheat cat's-ear noodles, buckwheat noodles (vermicelli), pancake, griddlecakes, jelly noodles, and porridge, etc. These foods are famous and popular in China, particular for their long history, rich nutritional profile, special flavor, various processing methods, and "functional food" role in maintaining human health. For example, buckwheat helao (hele), wantuo, and cat's-ear noodles are well-known local foods in northern region of China (Shanxi and Shaanxi provinces).

In Japan, buckwheat noodles called soba and buckwheat roasted-groats have long been very popular, while in Korea a favorite jelly-type food called "mook" is also made from buckwheat. In India, buckwheat flour is used for making "chillare," an unleavened bread fried with ghee and also for a crisp food called "pakora." Honey produced from common buckwheat is prized in both China and India. In Eastern Europe, buckwheat grain forms an important part of the traditional diet. Buckwheat groat porridge and meals as well as soup made from flour are still favorite traditional foods in Poland, Russia, and other some Eastern European countries. In the United States, although buckwheat is mainly used for animal feed, buckwheat cake was once a special breakfast item and buckwheat flour is also an ingredient of some pancake mixes.

Modern buckwheat food products include buckwheat dried noodles or vermicelli, instant noodles, spaghetti or macaroni, biscuits, breads, cakes, pastry, breakfast cereals and snacks, vinegar, drinks and

Beijing and New York: Science Press).

beverages (tartary buckwheat tea, buckwheat beer, and liquor). Most of these products, particularly made from tartary buckwheat, are popular healthy foods in China. Tender buckwheat shoots are used as fresh vegetables, and are also processed into canned vegetables.

Buckwheat Processing and Development

Buckwheat grains are de-hulled and milled into flour for food processing. Buckwheat flour milling is similar to wheat dry milling. Buckwheat flour yield ranges from 58% to 75%, mainly depending on variety and milling techniques. Buckwheat flour contains similar levels of starch and protein to wheat flour. However, the behavior of buckwheat flour is different from wheat flour and it is difficult to make wheat flour-like foods because there is no gluten. Therefore, buckwheat flour is usually mixed with wheat flour and other flours before use.

Chinese researchers and food factories have mixed buckwheat and wheat flour along with other flours to successfully make buckwheat pastry, sandwich-cake, dried noodles, instant noodles, and spaghetti (Tables 7 and 8). The processing steps for dried noodles are shown in Figure 1. Suitable levels of buckwheat flour are ~10% for crisp pastry and cakes, 20–40% for noodles, and 30–50% for palatable spaghetti. The cooking quality of spaghettis mixed from different ratios of buckwheat and wheat flours are shown in Table 8. Buckwheat/wheat spaghettis generally have higher water absorption, higher cooking loss, and higher protein loss rate than pure wheat spaghetti, because buckwheat flour contains much more albumins (water soluble) and globulins (soluble in salt water) than wheat flour. These commercial foods are produced by modern food-processing equipment. However, most traditional buckwheat foods are still hand-made in the countryside and even cities in China. An example of the basic hand-preparation method for buckwheat helao is shown in Figure 2.

In Japan, there are many noodle-making factories producing soba noodles. Buckwheat flour used for making soba is commonly mixed with 10–50% wheat flour. These noodles are sold in precooked, boiled, dried, or instant stages, as well as being made for direct sale to buckwheat noodle restaurants, small shops, and stands. In Europe and the United States, buckwheat flour is mixed with other cereal flours to make pancakes, flakes, biscuits, bread, noodles, spaghetti or macaroni, and ready-to-eat breakfast cereals. The processing of these foods can be conducted using ordinary baking, extruding, or expansion methods. The amount of buckwheat flour added to other cereal flours is generally less than 50%. For instance, acceptable bread contained 25% buckwheat flour with a formulation that included vital gluten, whey, or sour milk. A recipe for bread with 10% tartary buckwheat flour is shown in Table 7. It was also reported that the buckwheat-corn flakes were produced by extrusion processing. The formulations with an addition of 18%, 22%, and 33% buckwheat flour were used. The addition of 30% buckwheat flour gave the best organoleptic properties.

Although buckwheat is still cultivated as a minor crop in the world, buckwheat product development

has quickened since the 1990s, particularly in China. To date there has been an emerging trend in the research and development of high value-added buckwheat products. Tartary buckwheat has high potential in the health food market. Since tartary buckwheat contains a high level of flavonoids and other therapeutic components, some cosmetics and medicine products have successfully been developed and marketed using buckwheat materials in China, such as cream, shampoo, lotion, toothpaste, flavonoid capsules, etc. However, many such new products have not been accepted well in the marketplace, because of their high cost and erratic quality control.

Nowadays buckwheat functional foods and related products have attracted widespread interest and have become more popular. Much more attention should be paid to the biological functions, palatability, and acceptability of buckwheat products. It is necessary to enhance development and commercialization of traditional buckwheat foods and to improve modern buckwheat food-processing techniques.

Principal Ingredients in Cake Batter

Flour is the most important ingredient in cakes, functioning primarily to establish crumb structure. Cake flour is milled from soft white or red wheat with low protein and ash (mineral) levels and has a fine particle size. In the USA, cake flour is commonly treated with chlorine gas, causing hydrolytic depolymerization of the starch molecules, which increases the water-holding capacity of the flour. During mixing, proper gluten development is critical, to ensure a fine foam structure without excessive toughening. Protein level and type and mixing procedure are key factors for producing cakes with desirable crumb texture. The optimal specifications for a typical cake flour are: protein content $8.5\% \pm 0.5\%$, ash content $0.36\% \pm 0.04\%$, pH 4.7 ± 0.2, and average particle size $10\,\mathrm{mm} \pm 0.5\,\mathrm{mm}$.

Shortening performs three basic roles in cakes. First, it aids in aeration or leavening of the batter and finished cake by entrapping air during the creaming process. These minute air cells provide the nucleus for bubble expansion via steam and carbon dioxide during baking. Second, shortening coats the protein and starch particles, preventing hydration and formation of a continuous gluten–starch network. Third, it emulsifies liquids in the batter, which increases the moisture of the crumb. The last two functions contribute to a soft, tender crumb texture.

Eggs perform a variety of functions in cake production, providing structure, volume, tenderness, and nutritional quality to the product. They act as a binding agent due to their high protein content and ability to form a complex network with gluten. They contribute to cake volume and structure by their ability to be whipped into a relatively stable foam. Upon heating, the proteins are denatured, thus setting and stabilizing the crumb structure. The yolk portion of the egg imparts an emulsifying and tenderizing effect because of the high lipid and lecithin content. Eggs help stabilize the emulsion, retain gas generated by the leaveners, and prevent air cell coalescence in the batter, resulting in a uniform crumb grain and desirable texture. Eggs also add a mild but distinctive flavor and color (from the yolk) and enrich cake's nutritive value.

Chemical leavening agents are added to aerate the batter and produce a light, tender, porous product. The porosity of the batter directly translates into good volume, uniform cell structure, bright crumb color, tender texture, and overall eating quality of the finished cake. In lieu of yeast, chemically leavened cakes utilize sodium bicarbonate (baking soda) plus an acidic agent to generate carbon dioxide (CO_2) gas when combined in the presence of water.

Baking powders are a combination of sodium bicarbonate and the salt of a weak acid. Baking powder should yield no less than 12% carbon dioxide based on the weight of the product. Starch or flour may be added as a diluent to standardize the baking powder's strength.

Baking powders are classified by their reaction rates as fast-, slow-, or double-acting. The fast-acting types release most of their available carbon dioxide within the first few moments of contact with liquid. If these batters or doughs are not processed very quickly, the gas will be lost before the structure is set and the volume will decrease significantly.

Slow-acting baking powders do not react at low temperatures and therefore require oven heat to release gas. Double-acting types react partially at low temperature, but need higher temperatures to complete the reaction. The double-reacting powders are most commonly used in commercial cake production.

The neutralization value (NV) is used to give the proper balance of the alkaline and acidic agents. The NV indicates the amount of sodium bicarbonate required to release all the available carbon dioxide from 100 units of the acid leavener. NVs enable the formulator to achieve the desired batter pH, which is important to crumb structure and grain, color, and flavor.

Sugar acts primarily as a sweetener in cakes and aids in air incorporation during creaming. In the mid-1900s, emulsified shortenings enabled bakers to produce richer cakes with higher sugar and liquid levels. These high-ratio cakes generally contain 120% sugar, based on flour weight, and have an extended shelf life and tender texture. The type and form of sugar used are also important; liquid sugar or syrup acts as a moistener, whereas crystalline or granular sugar functions as a drier. Granulation affects how quickly the sugar dissolves and generally increases cake volume as granulation becomes finer. Invert or reducing sugars, e.g., high-fructose corn syrup, honey, or molasses, can affect the crust and crumb color, and texture.

Milk, either in fluid or dry powdered form, is a source of protein and lactose, which aid in crust development and browning reactions. Milk also stabilizes the foam and contributes to cake structure. Finally, salt is added as a flavor enhancer.

Formula balance of the major cake ingredients – plus or minus flour, shortening, sugar, and eggs – is important to produce a cake with good volume, grain, texture, and eating properties. Some general guidelines for high-ratio cakes are as follows:

- the weight of the sugar should be greater than the flour weight;
- the weight of the eggs should exceed the weight of the shortening; and
- the weight of the total liquids (milk, eggs, and/or water) should be slightly greater than the sugar weight.

Some exceptions to these rules include foam-type cakes, i.e., angel food and sponge, which contain little or no shortening. In these cakes, whipped egg whites, sugar, and flour are the primary ingredients, along with some minor ingredients. In a typical angel-food cake formulation (Table 1), the weight of the sugar is usually equal to the weight of the egg whites, and the flour is approximately one-third the weight of the sugar. Figure 1 shows the relationship between basic ingredient composition and cake type.

Table 1 Angel food cake formula

Liquid	214	110	59	150

Figure 1 Relationship between cake type and basic composition based on 100 parts flour. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 762, Elsevier Ltd.)

Sponge cakes use whole egg instead of only egg whites. To minimize the toughening effect of the eggs, an equal or slightly higher amount of sugar is added. The liquid and flour levels are balanced around the eggs and sugar. In general, the total liquids should be 25% greater than the weight of the sugar.

Flour level should be less than the weight of either the sugar or eggs. Combined, the weight of eggs plus flour should exceed the weight of sugar plus nonegg liquids (milk or water). A typical sponge cake formula is listed in Table 2.

Pound cake is one of the oldest cake types, deriving its name from the original recipe, which suggested one-pound (0.45 kg) increments each of flour, butter, eggs, and sugar. The expense of butter and eggs prompted commercial bakers to modify the formula, producing a lighter cake with improved volume and eating quality (Table 3).

The modified pound cake formula led to the basic yellow or white layer cake (Table 4). Unlike yellow layer cake, no yolks are used for white layer cake. These layer cakes adapt readily to many formula variations by the addition of fruits, nuts, spices, cocoa, etc. In chocolate layer cakes, the sugar level appears higher, which is due to a reduction in the flour level when cocoa is added. Functionally, low-fat cocoa acts much like flour. High-ratio cakes evolved from layer cakes through the use of emulsified shortenings and may contain as much as 140% sugar (based on flour weight).

Chemical and Physical Changes during Mixing

Mixing plays an important role in the production of quality of batter-type cakes. The objectives of mixing are to disperse the various ingredients uniformly, and to incorporate air into the batter while minimizing gluten development. There are four different basic methods of mixing: creaming, blending, single-stage, and foam-type methods.

In the creaming, or conventional method, fat and sugar are mixed at low-to-medium speeds until thoroughly blended and aerated. Large volumes of air are incorporated into the fat phase in the form of small air cells and the sugar crystals are encased in the shortening. Next, the eggs are added with continuous beating until the mixture is fluffy and well aerated. Last, the flour and milk are added. The main advantages of this method are: (1) the large number of small air cells in the batter; and (2) gluten development is limited due to delayed hydration and solubilization of the fat-coated flour and sugar particles.

The blending method consists of two separate mixing steps. The shortening and flour are beaten until fluffy in one bowl and the eggs and sugar are whipped separately in a second bowl. These two mixtures are blended together followed by slow addition of the milk. This method produces a cake with a very fine grain and uniform texture. Compared with the creaming method, aeration is lessened, thus reducing cake volume, but higher sugar and liquid levels are possible.

The single-stage mixing method was devised to reduce the number of steps and shorten the mixing-time requirements. All the major ingredients are mixed together at once. Although the procedure is simple, the texture and stability are sacrificed somewhat. This method is generally used for premixed box cakes, but not by the wholesale trade.

Unlike shortening-based cakes, foam cake mixing depends on air incorporation in an egg-protein matrix for volume and structure development. Egg whites plus sugar are whipped into a stiff foam, into which the flour and other dry ingredients are gently folded. In angel-food cake batters, the egg whites must be fat free to achieve maximum volume; however, in sponge cakes where whole eggs are used, a lower-volume, emulsified foam is formed.

The batter specific gravity is a measure of how much air has been incorporated into the batter during mixing. It is defined as the ratio of the weight of a known volume of batter to the weight of the same volume of water, at a given temperature. Batter specific gravity is directly related to the volume, texture, and grain of the finished cake. In general, the lower the specific gravity, the higher the finished cake volume, but optimal ranges for different types of cake batters have been established.

Chemical and Physical Changes during Baking

Air bubbles, creamed in the fat, are released into the aqueous phase as the fat is melted at ~40°C. Carbon dioxide is generated by the baking powder and collects in these air bubbles. As the batter heats, the batter begins to flow, due to natural convection currents, because the batter temperature next to the sides and bottom of the pan increases first and that in the center heats last.

The batter viscosity decreases initially upon heating as the fat melts and before the starch gelatinizes. Between 60°C and 70°C, the starch granules absorb several times their weight in water, increasing the batter viscosity considerably. Major swelling of the gelatinized starch granules insures that the cake structure will not collapse. The amount of sugar and some emulsifiers in the formula control the temperature at which the starch gelatinizes. The cake normally sets into a solid system well below the boiling point of water (100°C).

As the batter temperature reaches ~80°C, the air bubbles enlarge rapidly, causing the cake to rise. The liberation of carbon dioxide, the expansion of air cells, and the formation of steam – all contribute to the leavening effect. Heat causes the gas to expand and the pressure inside the gas cells to increase. Resistance to expansion results from protein coagulation and starch gelatinization. Timing is critical for the protein film to enlarge with the expanding gases, prior to protein denaturation and starch gelatinization, which set the structure. Emulsifiers, whether occurring naturally in eggs or added, improve the elasticity of the protein film surrounding the gas bubbles, enabling them to increase without rupturing.

Moisture evaporates from the cake surface during baking, keeping it cool. However, as most of the water is removed, the surface gets hot enough to brown. Lower baking temperatures should be used for richer (high sugar and fat content) cakes, as the sugars can cause excessive browning of the crust before the interior is set. The baking time for all cakes should be kept as short as possible to avoid too much color development and formation of a thick crust.

A summary of common cake faults and possible ingredient, mixing, or baking-related causes is given in Table 5.

Role of Additives

One of the main additives in cake production is added to the flour itself. In the USA, cake flour is made by adding chlorine gas to soft wheat flour at a rate of 0.3–1.5 g per kg (0.5–2.5 oz per 100 lb) of flour. This lowers the pH and improves overall baking performance by increasing the volume, and improving grain, texture, and symmetry. The optimal pH range is between 4.5 and 4.8. The mechanism of chlorine on flour

Table 5 Troubleshooting guide for cakes

is not completely understood: various researchers have shown that it affects the gluten, starch, and/or lipid components of wheat flour.

Over-chlorinated cake flour will cause the batter to set too quickly around the sides of the pan before full expansion has been reached. The center continues to rise, and the result is a cake with a strong peak. If the flour is under-chlorinated, the structure sets too slowly, allowing the leavening gases to escape, and the center of the cake collapses upon cooling.

Emulsifiers promote air incorporation in the form of fine bubbles and disperse the shortening into small-sized particles. Emulsifiers' unique behavior is due to their ability to bridge the inseparable oil and water phases at the interface. When their concentration exceeds the solubility limit, they form an interfacial membrane whose hydrophilic portions extend into the aqueous phase. The membrane surrounds the dispersed oil and prevents the emulsion from breaking.

Hydrogenated shortenings typically contain 3% emulsifiers, with glycerol mono- and di-stearate being the most common, although many others, including blends, are also used.

Antioxidants are sometimes added to cake mixes to retard the development of oxidative rancidity during storage. All fats are subject to oxidative and hydrolytic rancidity, which causes objectionable odors and flavors, but antioxidants delay these reactions from occurring within the products' shelf life. Four compounds commonly used as antioxidants are butylated hydroxyanisole, butylated hydroxytoluene, *t*-butyl hydroquinone, and propyl gallate. Citric and phosphoric acids have a synergistic effect when combined with the antioxidants. The levels are limited by law, economics, and functionality, and vary with the additive and product application, but generally fall between 0.005% and 0.1% of the product weight. Natural antioxidants, e.g., tocopherols, offer a desirable alternative to synthetic varieties, but have other usage issues such as heat lability.

Color additives are used in many baked products, including cakes and their icings. Added color can help the product fulfill consumer perceptions and expectations regarding quality, richness, and overall visual appeal. There are two types of color additives – certified and uncertified. The certified colors are synthetic and strictly regulated, whereas the uncertified usually come from natural sources, and usage level varies greatly. The certified colors used in the USA include FD&C blue no. 1, FD&C red no. 3, FD&C yellow no. 5, and FD&C red no. 40. Uncertified color additives include annatto extract, β-carotene, beet powder, β-apo-8-carotenal, xanthins, caramel, carmine, carrot oil, cochineal extract, toasted partially defatted cottonseed flour, fruit and vegetable juices or concentrates, paprika and paprika oleoresin, riboflavin, saffron, titanium dioxide, tumeric, and tumeric oleoresin.

Many flavoring agents are used in cake batters, icings, and/or fillings. Spices are processed from different parts of aromatic plants, including fruits, barks, or seeds. Some spices commonly used in cakes include allspice, anise, caraway seed, cardamom, cinnamon, cloves, coriander, ginger, mace, nutmeg, poppy seed, saffron, and sesame seed. Some of these act as both flavoring and coloring agents.

Alcohol extracts can also be used to enhance the flavor of cakes. The sapid and odorous volatile components are extracted from aromatic plants or parts of the plant and solubilized in ethanol or propylene glycol. For example, vanilla extract is a ubiquitous flavoring in cakes, derived from the vanilla bean.

Chocolate and cocoa from the cacao tree bean are also popular flavoring agents. However, defatted cocoa powder also adds bulk to the cake, often replacing up to 10% of the flour weight. Often in chocolate cakes, the sugar level and leavening system must be adjusted to compensate for the cocoa.

CAKES, PASTRIES, MUFFINS, AND BAGELS

D E Ortiz, WK Kellogg Institute, Battle Creek, MI, USA

Introduction

Cakes, pastries, muffins, and bagels constitute a rich and diverse topic. It is probably easiest to think of cakes and muffins in one group of chemically "leavened," batter-based products, and pastries and bagels as a separate group of dough products, some yeast leavened and some not. All of these products are sold at local grocery stores and bakeries, and have also been taken to high art forms by pastry chefs and artisan bakers. These products have also been successfully scaled up to production lines churning out thousands of pieces an hour. Many of these large production lines produce elegant versions of these products with very little handwork.

Cakes

The variety and diversity of cake products and formulations within the United States are quite large. Also, cake flour and cake formulation vary substantially across the globe. Putting it simply, in the United States, most industrially produced cakes are baked using a high-ratio formula (more sugar than flour) and chlorine-treated cake flour. Most European cake formulas, however, use a lower level of sugar and soft pastry flour.

Bakery items classified as cakes are generally batter products that are relatively high in sugar, fats, eggs, dairy ingredients, and flavorings. Baking powder and air incorporation are common leavenings. Although there are a few savory products that could be labeled as cakes, in general cakes are sweet flavored and have a tender bite. In the United States, there is a subclass of pastries called "coffee cakes" or Danish pastries. These products will be addressed in the section on pastries, as most of these products are yeast leavened instead of chemically leavened.

Cakes are generally categorized by their ingredients and mixing procedure. The most common cake is the "butter" cake that is mixed by creaming the shortening together with the sugar to incorporate air. Air is further entrapped with the addition of eggs to the creamed mixture. Foam-type cakes such as angel food or sponge cakes rely heavily on the eggs in the system to incorporate the air cells. In the past, these products were made by whipping eggs or egg whites separately from the rest of the batter ingredients and then carefully folding the whipped eggs into the system. With the advent of current emulsifying systems, sponge cakes can be made as a single-stage mix by adding hydrated, blended emulsifiers.

In general, batters contain more water or fluid ingredients than doughs. The distinction between doughs and batters is not clear, but usually batters are pourable and flowable in a short period of time (of the order of seconds). Doughs often require cutting to separate a portion of the dough from the mass. Although doughs flow over time, they cannot be easily poured and their flow is generally measured over a time of the order of minutes.

One of the earliest recorded recipes for cakes was a household recipe for pound cake that contained a pound each of flour, butter, sugar, and eggs. Many early bakeries essentially followed this outline for years with individual bakers modifying the formula to vary the butter and egg level and adding milk. After the advent of finely milled patent flour that was chlorine treated in the 1930s' America, formulas were more dramatically altered to have higher levels of sugar than flour. This was the advent of the "high-ratio" layer cakes. These high-ratio cakes contain between 100% and 140% sugar on a flour weight basis (fwb) as compared to a sponge-type cake with 30–45% sugar on flour weight basis (Table 1).

Table 1 Sample high-ratio cake formulas (percentages on fwb)

Ingredient	*Yellow*	*Sponge*	*Devil's food*
Flour, chlorine treated cake	100.0	100.0	100.0
Sugar	135.0	45.0	135.0
Shortening	55.0		50.0
Milk, nonfat dry	4.0	3.0	4.0
Eggs, dry whole	12.0		12.0
Eggs, dry whites	3.0		3.0
Eggs, liquid whole		100.0	
Baking soda		1.0	2.0
Baking powder, double acting	0.6		2.0
Salt	1.0	1.5	1.5
Cocoa, alkalized red			16.0
Water	130.0		180.0
Hydrated sorbitan monosterate		4.0	
Invert sugar			15.0

Flour for Cakes

Cake flour in the United States is generally milled from soft red wheat grown in the Ohio River valley states (Ohio, Indiana, Illinois, and Michigan). This type of wheat is also grown in some more southern states such as Missouri, Arkansas, Tennessee, and Texas. The millstreams collected for cake flour are typically those lowest in ash content with an extraction rate of 50–75%. This flour has a small particle size compared to a bread-type flour and is often treated with gaseous chlorine. Most importantly for cakes, the gluten must be of a quality that aids in the forming of films for trapping gas in small air bubbles, but not the quality that lends the toughness/chewiness commonly found in bread flours.

Gaseous chlorine is used as an improver of soft wheat flour for cakes in the United States alone. Gaseous chlorine reacts with nearly all of the components in flour and has profound effects on many of them. Some of the effects of chlorine on flour include bleaching of pigments by addition across conjugated double bonds, lowering pH of flour slurry by freeing of hydrogen ions from pigments, lipids, proteins, and starch, and oxidizing and depolymerizing starch. Most of the chlorine gas reacts first with the lipid and water-soluble fraction. The end result of the addition of gaseous chlorine is that the cake batters are better able to expand during baking and collapse less upon removal from the oven.

In the European Union, law bans the use of chlorine gas to treat flour. Alternative treatments such as heat, light, and ozone treatments have been investigated and currently some cake flour is heat-treated to "improve" the baking quality of the flour. This improvement gives small changes in the flour quality to improve the cake baking quality but not the dramatic changes seen with chlorine gas.

Shortenings

The other major technology improvement was the advent of "emulsifiers" and new emulsified shortenings which were much more consistent than their simpler nonemulsified counterparts. Air cells cannot be added to the mass by any means other than mechanical agitation. The gases created by chemical leavening or by steam "add" to the volume of the air cell created during mixing, but cells are "created" during mixing. The industry has found several methods for aiding in the formation of these cells and protecting them, once formed, by changing the surface tension of the material at the cell/mass interface. Emulsification is one method that protects air cells by changing the surface properties of the interface. Common emulsifiers for cakes such as lecithin or mono- or diglycerides have a "hydrophilic" and "hydrophobic" region on the molecules. This allows the materials in the batter to interact more closely and in thinner sheets. This results in better dispersion of the emulsified shortening throughout the batter, forming smaller, more uniform air cells, which in turn produce a tender cake with a fine texture.

Sweeteners

In most parts of the world where granulated sugar prices are low, granulated sugar is the exclusive sweetener found in cakes. Granulated sugar imparts sweetness and tenderness to the texture of the finished cake. The crystalline structure and granulation size of the sugar helps in formation of air cells in the batter, and it contributes to the viscosity of the batter. In the United States, where sugar prices are higher, it is common to substitute part or all of the sugar with high fructose corn syrup (HFCS). When this change is made, there are many formulation changes that are required to make a similar cake. Because liquid sugars introduce more liquid to the cake batter, as well as reducing sugars, the cake formula must be altered. These changes include varying the fat level and/or type, changing the emulsifier level and/or type, and changing the liquid levels. The risk one takes when making these changes is that the high level of "reducing sugars" in the presence of protein in eggs and milk common to most cakes results in a product which is darker in both crust and crumb.

Low-in-sugar or "no sugar" cakes can also be made in several ways. The first is by adding one of several high-intensity sweeteners coupled with a bulking agent such as polydextrose. Another method is to substitute sugar alcohols such as sorbitol or xylitol for the sugar in the formula. Lastly, a new variety of sweeteners that are based on sugar (i.e., sucralose) can be substituted one-for-one for sugar. All of these methods will likely require some modification of the formula ingredients and process to compensate for the changes in viscosity and eating character of the cake when sugar (sucrose) is removed.

Leavening

Leavenings are a critical factor in aiding the formation of the aerated structure one expects to find in cakes and cake batters. Chemical leavenings commonly found in cake formulations are blends of leavening acids and sodium bicarbonate. The action of the acid portion of the leaveners is largely dependent on the temperature at which the acid reacts with the sodium bicarbonate in the solution, as well as on the level of bicarbonate present. Some acids that are quick to solubilize are leaveners like monocalcium phosphate

(MCP) monohydrate and some of the fast acting sodium acid pyrophosphates (SAPPs). These largely react in the mixing bowl to add gas to the batter, thus adding volume and viscosity to the batter while it is being mixed. Other acids require the higher temperatures of the oven to solubilize. These include the most common second acid in double acting baking powders, sodium aluminum phosphate (SALP), some slow acting SAPPs, and sodium aluminum sulfate (SAS). Double acting baking powders are designed to include both primary acids that solubilize at room temperature during mixing and secondary acids that solubilize in the oven at elevated temperatures.

When designing leavening systems for cakes or any other chemically leavened food products, it is important to balance the alkaline component (sodium bicarbonate) with the acid component or components to achieve complete neutralization in the finished food. Leavening blends may be formulated by mathematical calculation using an equation called the "neutralizing value" (NV). NV is defined as the weight of sodium bicarbonate required to completely react with 100 parts by weight of a leavening acid. This is captured by the following equation:

$$\mathrm{NV} = \frac{\text{g of sodium bicarbonate} \times 100}{100\,\text{g of acidic salt}}$$

Neutralizing values for many common leavening acids have been included in Table 2.

Other Cake Ingredients

There are a number of minor ingredients and flavoring ingredients that are used in modern cake production. It is difficult to find a cake produced in the United States without a modified starch or a gum. Modified starches and gums help to add viscosity during processing. This helps in stabilizing the air cells and thus in producing a fine textured, soft cake. These ingredients also act as a tenderizer by diluting the flour and help maintain moistness in the cake throughout storage. There are also very few cakes made without vanilla or vanillin or other flavoring ingredients. One very important additive is cocoa or chocolate.

Melted chocolate can be added to many cakes during the creaming stage of mixing along with the shortening and sugar. These cakes can be labeled in the US as chocolate cake. More often, cocoa is used to impart the "chocolate" flavor and color as desired by consumers. These cakes cannot be labeled as "chocolate." However, there are several common names that are used for these cakes such as "devil's food" or "fudge." Cocoa is commonly added to cakes either in the creaming stage or in the last stage of mixing along with the flour. In the latter method, the cocoa is usually sifted with the flour to prevent clumping of the cocoa, as it is a rather hydrophobic ingredient. The cocoa used in cakes is usually treated with alkali to produce dutched cocoa; therefore, controlling the pH of the finished cakes is very important because it affects the color and flavor of the finished product. Natural, or untreated, cocoa is often used in frostings, icings, and fudge. Control of the pH in all "chocolate" cakes has a large impact on the flavor and color of these cakes. As a result, many of them are baked with sodium bicarbonate only to ensure that the pH stays in the alkaline region.

Table 2 Types of leavening acids and their neutralizing value

Leavening acid	*Common abbreviation*	*Neutralizing value*
Dicalcium phosphate dihydrate	DCP	33
Monocalcium phosphate	MCP	80
Monopotassium tartrate	Cream of tartar	45
Sodium acid pyrophosphate	SAPP	72
Sodium aluminum phosphate	SALP	100
Sodium aluminum sulfate	SAS	100

Pastries

Pastries are defined as any products made from any of several different doughs that include fats, flour, and water. Examples of pastry include puff pastry, pie dough, or pate sucree (a sweet short pastry). Pastries can also be a general term for sweet baked goods such as Danish pastries or coffee cakes. This is a broad and diverse category of bakery products. It is easiest to divide pastries into dough products that are laminated and those that are not (Table 3).

Table 3 Sample pastry formula (percentages on fwb)

Ingredient	*Puff*	*Danish*	*Pate sucree*
Flour, pastry	100.0	25.0	100.0
Flour, bread		75.0	
Sugar, granulated		20.0	
Sugar, powdered			38.0
Eggs, liquid whole		20.0	0.5
Egg yolks, liquid			32.0
Water, cold	50.0	50.0	
Salt	2.0	2.0	1.5
Shortening or butter	75.0	20.0	45.0
Yeast		7.0	
Milk, nonfat dry		6.0	
Vanilla extract			0.1

Laminated Doughs

Laminated dough products can be further subdivided into those that contain yeast and those that do not. The latter are commonly referred to as "puff pastry." The products that do contain yeast include the broad category known as Danish pastries as well as croissants. In both of these types of products, development of gluten structure is important to the finished product quality. The dough for all of these products must be able to tolerate the stresses in multiple passes through reduction rollers without ripping. In general, the yeasted laminated products are made with slightly lower protein content flour than the puff pastry products. But for all of these products, flour quality and laminating shortening quality are equally important. Processing conditions and resting of the dough between times of stress also play an important role in manufacture of great laminated dough.

Flours used for puff pastry vary from region to region. In the United States, it is not uncommon for pastry chefs to use "bread" flour with a protein level of 11–12% for their puff pastry. This high-quality flour with a relatively high protein level allows the dough to sheet into very thin layers between the layers of fat. In the United Kingdom, where flours tend to have less gluten strength, it is not uncommon for the flour to be supplemented with additional vital wheat gluten to give the final dough the strength that is needed to form the products. This practice may not be appreciated by traditional pastry chefs who roll their laminated doughs by hand, but with the rigors of mechanical sheeting, doughs have different levels of stress placed on them and fortification with gluten may be required to handle the added stress. Some processors of laminated doughs mix the flour, water, and other minor ingredients into a well-developed gluten structure prior to mixing fat to the dough. They believe that this helps shield the proteins from abuse during sheeting. More likely, it just shortens the mix time by allowing the gluten protein matrix to develop before the shortening is added. Shortening lubricates the flour and protects it from absorbing water as quickly, slowing hydration of the gluten proteins; therefore, it usually requires longer mix times to develop the gluten.

Fats or shortenings are used in two ways in laminated doughs. "Dough fat" is the shortening that is added to the flour and water and other ingredients that comprise the dough. "Laminating fat" is the shortening or butter that is formed into thin layers between the thin dough layers during the sheeting and folding of the dough. This laminating fat is also often referred to as "roll-in" shortening. Danishes and puff pastries use butter, margarine, or vegetable shortening as laminating fats. In any case, the laminating shortening must be relatively plastic at the cool temperatures used to make most of the doughs (10–20°C). The laminating shortenings must also have a controlled melt point of 39–44°C so that they do not taste waxy upon consumption. Some roll-in margarines and butter contain a significant amount of water but many commercial bakers prefer the control and crisper texture that they get with butter, lard, or shortenings that are devoid of water.

Water is very important in laminated products for the formation of a dough as well as to aerate the products through steam expansion. As steam leaves the dough or the laminating fat during the heat of baking, it pushes against a solid barrier layer of the laminating shortening, pushing the layers of dough apart to create the height and flakiness desired in the product. Increase of water level in the dough of laminated products has little effect on the finished product, but can affect the sheeting and handling properties of the dough. If too little water is added to the dough, this can restrict the dough during proofing and baking and give a final product that is low in volume.

Sugar, egg, and milk added to the dough of laminated products can greatly influence the final finished product. Sugar not only increases the sweetness of the dough and finished product, but also can decrease finished height while increasing shrinkage when added at levels up to 20% (fwb). In general, adding sugar to dough tends to soften the dough, increasing the dough stickiness, and difficulty in sheeting. Sugar also contributes to the color of the finished product. One important consideration when using high levels of sugar in yeasted pastry doughs is that the high sugar levels inhibit the yeast fermentation by elevating the osmotic pressure. On the other hand, levels of sugar below 12% (fwb) have not been reported to inhibit fermentation for most common yeasts used in baking.

Small levels of egg added to pastry doughs can provide some additional protein support to the products as well as the emulsifying benefits of indigenous lecithin. Pastry products with up to 3% egg yolk tend to bake taller and are more tender. At higher levels of egg, the color and flavor of the egg become evident and can contribute to inappropriate browning and off-flavor development.

Much of what makes the laminated doughs so popular with consumers is the shaping and forming of the doughs with added fillings and toppings. It is not uncommon in local bakeries and in full-scale production facilities to see croissants made not just plain but with fillings such as chocolate, apple, sweet almond paste, raspberry, and cream cheese, or a full-scale breakfast such as scrambled eggs and cheese. Coffee cakes are

often braids of these sweet, laminated doughs with apple filling and streusel topping. Many of the dough formulas vary little, but the shapes, fillings, and toppings are endless.

Short Doughs, Pie Doughs, and Pate Sucree

Short doughs and pie doughs are slightly sweet and very rich doughs containing high levels of fats. Pate sucree is also a very rich dough, but it is also high in sugar, similar to a shortbread cookie. Pate sucree can contain up to 50% butter (fwb) and 30% sugar (fwb). Pate sucree and pate sablee are both short doughs with similar formulas. The two doughs differ only in their production methods.

Many short doughs and pate sucree are made in similar fashion. The first step is creaming of the shortening or butter with the sugar. The second step is creating an emulsion with the liquid ingredients, including eggs. The last step is the addition of dry ingredients, including flour and leavenings.

Pie doughs and "pate sable" are made differently. With this product, the shortening is cut into the dry ingredients including the flour and sugar until fine, and the liquid ingredients are added last. The two different mixing procedures give different finished products with the short doughs and pate sucree having a less tender bite and the pie doughs and the pate sablee being more tender, and in the case of pie doughs, flaky texture.

Muffins

The history of the bakery item that we now call "muffins" is not clear. There are several distinct foods that bear the muffin moniker. "English" muffins are toast-able rounds that are split in the center and generally served as a toast replacement. The "English" muffin is generally baked in a round form on an oven band and is a simple formula with little additional sugar and fat. The bakery muffins that are addressed in this article are readily identifiable by their shape. The muffin shape comes from baking in a "cupcake" or "muffin" pan. They are recognized by their stout "mushroom-like" shape. Muffins can also be identified by formulation. Most muffins are baked from a chemically leavened batter into a moist, coarse-grained mini-cake. Muffins range in formula from those that are rather low in fat, sugar, eggs, and milk to those that are richer in fat and sugar than many cakes.

Ingredients commonly found in muffins include flour, sweeteners, fats, eggs, milk, chemical leavening, salt, and characterizing ingredients such as bran, fruit, corn meal, chocolate chips, or chopped vegetables. The flours commonly used in muffins have to withstand the high levels of sweeteners and particulates. Although there are some muffin formulations that use the chlorine-treated cake flour used in high-ratio layer cakes, most muffin formulas are better suited to a blended flour of pastry flour and bread flour otherwise known as "all-purpose" flour. Some formulas even specify higher protein bread flour. The addition of the higher-protein flour helps create a product that is slightly chewier and coarser in crumb than a cake. Most US muffin consumers expect this chewier, coarser texture (Table 4).

There are some other carbohydrate-based ingredients that are added to some muffin formulas. Some modified starches and gums are added to lengthen shelf life by maintaining a higher-moisture product. In some muffin batters with large particulates or significant quantities of particulates, the batter viscosity can be increased by adding small amounts (0.05–0.2% fwb) of gums, like xanthan or guar. This increase in viscosity helps the particulates stay evenly dispersed throughout the batter during processing.

The most commonly used sweetener for muffins produced in a small-scale bakery is granulated sucrose. Other sugars may be used in these bakeries for specific uses such as honey or molasses to contribute a specific flavor profile or color. Corn syrup may also be used to help contribute color. In large-scale bakery operations, corn syrup or HFCS may be used to lengthen the shelf life of the muffin products. When adding these reducing sugars, care must be taken not to over-brown the products.

As with cakes, nearly every muffin formula has a substantial quantity of eggs and milk. In bakery mixes, these ingredients may be added as dry, powdered ingredients to the mix, thus reducing the likely

Table 4 Sample muffin formulas (percentages on fwb)

Ingredient	*Simple*	*Blueberry*	*Bran*
Flour, all purpose[a]	100.0	100.0	75.0[b]
Sugar, granulated	80.0	115.0	50.0
Shortening	30.0	85.0	35.0
Baking powder	5.0	2.0	2.0
Baking soda		1.5	3.0
Nonfat dry milk	4.0	4.0	10.0
Whole egg powder	10.0	7.5	5.0
Salt	1.5	2.0	1.5
Bran			25.0[b]
Molasses, light brown sugar			25.0
Honey		10.0	25.0
Water	65.0	70.0	100.0
Blueberries, fresh whole		80.0	

[a] All flour is all-purpose type except for the blueberry muffin which would require a chlorine treated cake flour.
[b] For the bran muffin, wheat-based ingredients (flour plus bran) equal 100%.

mistakes in baking and guaranteeing a more consistent product. Eggs are added to muffins to contribute their flexible proteins to the structure of the muffin. Also, eggs contain a natural lecithin that aids in mixing of the batters. Milk is added in large part because lactose and milk proteins contribute to the browning of the finished product.

Most muffins are deceptively high in fats. The average consumer is likely not aware that muffins can have more than 40% fat (fwb). Many muffins are made with vegetable oil (healthier for heart) rather than with a hydrogenated shortening, but muffins still contain a substantial amount of fat. Most muffin formulas do not require an added emulsifier unless very little egg is used in the formula. When emulsifiers are added, they are likely to be lecithin or mono- and diglycerides found in emulsified shortening.

Wide ranges of chemical leavenings are used in muffins – from the addition of simple sodium bicarbonate to a complex double-acting baking powder. Most muffins are rather simple in their mixing, with little air incorporation by whipping. Most of the air is trapped in large air cells, thus adding to the coarse texture of a muffin. There are some muffins made using a more cake-like formula and production method that will give a smaller air cell and a finer texture. Often the muffin formulas rely on a late acting acidulant such as SALP to aid in the formation of cell structure.

Leavening is also one of the major influences on the finished shape of the muffin. Most muffins have either a mushroom top or a simple peak top. Mushroom-topped muffins have a leavening balanced to force the batter to expand and flow before a crust is formed on the top surface of the muffin pan. Additional leavening, in the form of a late-acting acidulant, remains to push the center of the muffin up, thus forming the mushroom cap effect. These mushroom-topped muffins also are frequently richer in formula and have more batter in the cup than a peak-topped muffin. The peak-topped muffins are usually baked at a higher temperature (above 400°F) and the leavening is designed to act early in the baking process so as not to crack the top after the top crust is formed.

One of the characteristics of muffins is the addition of fruits, nuts, chips, wheat or oat bran, or other strongly flavored particulates. These additives can be added as fresh fruit (blue berries, peach, or apple chunks), whole or chopped nuts, chocolate or other flavored chips, or fabricated bits of flavored material. The addition of these ingredients adds to the perception of quality and overall wholesomeness of the muffin. Also, the particulates act to break the structure of the muffin and change the texture. Toppings are also common with muffins and can be as simple as a cinnamon/sugar blend or as complex as a nut streusel. Toppings are also often materials meant to "sink in" to the muffin creating a "filling" such as the addition of a sweet cream and cheese mixture. Again, this topping adds to the complex nature of the muffin, creating changes in texture and flavor as the consumer eats the product.

Bagels

Bagels have a unique history and formulation. The word bagel comes from the Yiddish word, *beygel*. Bagels are thought to have originated in Poland, where Polish bakers, in an effort to honor their victorious horse-riding king, made a stirrup-shaped roll and boiled it before baking. This boiling helped keep the shape of the roll during subsequent baking.

Jewish immigrants who moved to the Northeastern United States brought bagels to America. Bagels were made ubiquitous in the United States by a successful Polish-American baker, Harry Lender, and his sons, who used humor in advertising to reach out to middle America with a traditionally ethnic, northeastern food.

In general, bagels have a very simple formulation. The formula is very similar to simple bread or roll formulas: flour, salt, yeast, and water. What separates the bagel from the rest of the rolls is the flour quality and the processing. Traditional bagels were made with very high protein, spring wheat flour. The flour for bagels has often 13–16% protein content. Spring wheat grown in the northern plains of the United States and southern Canada produces most of the flour used in baking traditional bagels made today. Many major manufacturers of bagels use less expensive flour in the 12.4–13% protein range but still are forced to pay a premium for the higher protein content. The high protein content of the flour and the mixing of that flour to full development helps give bagels their characteristic chew (Table 5).

The other significant distinction for bagels is the processing. Traditional bagels develop much of their flavor

Table 5 Sample bagel formula (percentages on fwb)

Ingredient	*Plain*	*Egg*	*Onion*
Flour, high protein[a]	100.0	100.0	100.0
Yeast, dry	0.5	0.5	0.5
Yeast food	1.5	1.5	1.5
Salt	3.0	3.0	3.0
Sugar, granulated	5.0	5.0	5.0
Water[b]	65.0	70.0	70.0
Egg, whole powdered		4.0	
Onion, dry toasted			2.0

[a] Flour should have added malted barley flour.
[b] Water varies by flour requirements and by levels of dry ingredients requiring some hydration.

and distinct crust characteristics from a long, cold fermentation step called retardation. Among large-scale bagel makers, this retardation step has been either a bulk retardation of the whole dough mass or an individual fermentation of preformed bagels. The bulk retardation has more effect on flavor and internal crumb character than on crust characteristics. Piece retardation also affects flavor and crumb characteristics, but also has a significant effect on the crust characteristic. The air cells on the surface of the bagel collapse and the surface dries somewhat giving a thick, chewy crust after baking. This collapse and coalescence of cells is also seen in the crumb. Bagels that have been through a retardation process tend to have a more coarse, thick-walled cell structure than a nonretarded bagel.

The dough for bagels in high-speed production is divided in one of the many typical methods found in roll production. The formation of the ring structure is rather unusual and there are very few manufacturers of the equipment necessary to make the rings. One method deposits a dough ball on the end of a belt that moves the ball under a plate to form the dough into a cylinder and then around a mandrel to form the ring. These are called horizontal formers. The second method in a vertical former where the dough ball is dropped into a series of hinged cups that form the dough around a mandrel.

The last processing distinction for traditional bagels is the boiling process. The setting of the structure of the dough ring can be achieved through an application of moisture to the dough surface either through steam injection into the first zone of a tunnel oven or by moving the dough rings through a boiling water bath. This bath water can contain malt or sometimes a sugar but often it is just simple water that becomes saturated with starch and dextrins. There are advantages to both methods of water application, but the finished food is different. Boiled bagels tend to have a more distinct hole and a thicker, chewier, shiny crust. Steamed bagels tend to have a softer crust.

Bagels may, and often do, contain other ingredients. They can be made with a variety of added grains, fruit and vegetable pieces, nuts, spices, eggs, garlic, cheeses, etc. Bagels often contain dough modifiers such as fats, emulsifiers, malt, enzymes, and other processing aides similar to those typically found in roll or bread formulations. Shelf stable bagels frequently contain the typical preservative systems of breads (i.e., Ca or Na proprionate) and crumb softening systems. The crumb softening systems are usually a combination of starch-modifying enzymes and moisture-holding ingredients such as gums or modified starches. In general, bagels are lower in fat than some other baked goods, but sometimes bakers make up for this by addition of fat-containing ingredients such as cheeses.

Bagels are also often baked with toppings on them such as seeds, finely chopped onion, or salt. These toppings help contribute some of the characterizing flavor and appearance of flavored bagels. The toppings are often coated on the top of the bagels after boiling and before baking. If the bagels are baked using a steam-injected oven, the toppings may be adhered to the surface of the dough using a wash-like modified starch or a gum that acts as an adherent to keep the toppings on the bagel dough.

CANOLA

Contents

Genetics and Breeding

T Jinxing and F Tingdong, Huazhong Agricultural University, Wuhan, Hubei, People's Republic of China

There have been dramatic advances in the improvement of oilseeds over the past couple of decades. The improved quality has brought recognition to rapeseed oil as a nutritionally superior edible oil since the erucic acid content was decreased to zero, and to meal as an important source of protein for animal feeds after the glucosinolate content was decreased to 10–12 μmol g^{-1}. To emphasize these improvements, the term "canola" has been introduced to refer to seed and seed products of "double zero" cultivars in Canada, and then extended to the world.

Germplasm in *Brassica*

The botanical relationship between the *Brassica* oilseed species was established as a result of taxonomic studies carried out in the 1930s (see Figure 1, U's triangle). There were three primary species with a single cycle: *B. rapa* (A, $n = 10$), *B. oleracea* (C, $n = 9$), and *B. nigra* (B, $n = 8$). The secondary species with double cycles – *B. napus* (AC, $n = 19$), *B. juncea* (AB, $n = 18$), and *B. carinata* (BC, $n = 17$) – were amphidiploids derived from the primary species. These relationships have been confirmed by the artificial synthesis of *B. napus*. Recent studies using biotechnology also indicate that some revision of these species and related genera may be necessary.

There are totally ~43 000 genetic germplasm accessions in the world (see Table 1). The main cultivated species – *B. napus*, *B. rapa*, and *B. juncea* – account for three-quarters of all *Brassica* germplasm. *B. rapa* and *B. juncea* are the major parts, 34.09% and 27.2%, respectively. *B. napus* is widely grown, but accounts only for 14.32% of the germplasm. These data mean that *B. napus* lacks in genetic diversity. Breeders have resynthesized new *B. napus* by crossing or protoplasm fusion between *B. rapa* and *B. oleracea* according to U's triangle.

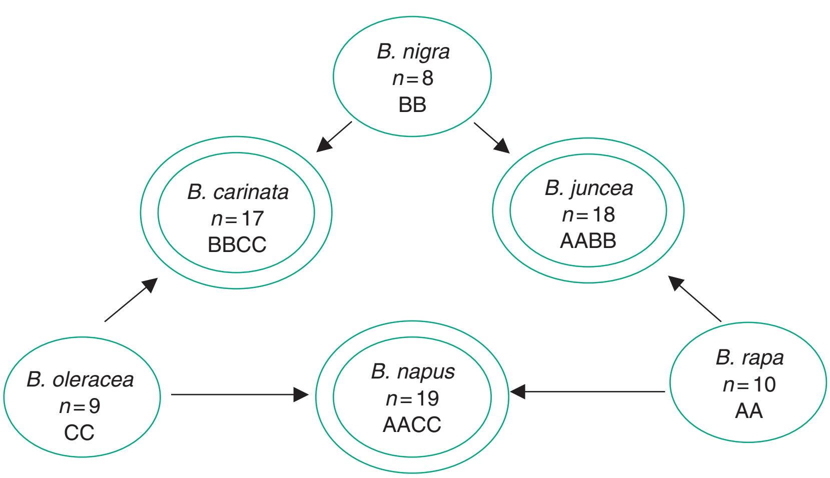

Figure 1 Genomic relationship of the *Brassica* species (U's triangle).

Table 1 Germplasm accessions of oil crops in *Brassicaceae*

Species	*Number*
B. rapa	14 631
B. juncea	11 705
B. napus	6 147
B. nigra	1 047
B. species	759
B. carinata	735
Sinapis alba	353
Eruca sativa	339
Crambe spp.	78
B. tournefortii	23
Camelina sativa	17
Total	42 919

Genetics and Breeding

Yield

Improvement for yield is a major goal in plant breeding. It is also very difficult to achieve. The measurement of yield is usually done in small plots. The yield of rapeseed is composed of three factors: pods per area (square meter), seeds per pod, and weight per one thousand seeds. All of them have shown a positive correlation with the yield, but the relationships between the factors are negative. The influence of environment on the yield of rapeseed is much more than that of cereals. The contribution of each factor to yield is different in different areas, so breeders select the different factors to improve the yield. For example, breeders in Sweden need to increase the weight per pod, but those in Poland must increase the weight per one thousand seeds. The number of pods in the main inflorescence is widely used. Since the yield is affected by many characteristics and the environment, breeders have proposed another approach to select for an ideotype. This ideotype is a list of desirable traits for a population that is expected to give higher yields because of greater efficiency in plant structure and in allocation of resources for plants.

Heterosis can also be utilized to increase the yield. Generally, hybrid yield is 20% more than that of the highest-yielding parent. There are three useable systems to produce hybrids in rapeseed. The first system is cytoplasmic male sterility (CMS), such as polima, ogura (kosena), nap, msl (male sterility Lembke). Hybrid seed production based on this system must have three lines: CMS line (A), maintainer (B), and restorer (R). An interval sowing of A and B is to maintain A line supplies. Another interval sowing of A and R is to produce hybrid seed. This method is very simple, and the cost is very cheap. The second system is genic male sterility (GMS). This way is not usually an economic method for hybrid seed production because of the need to remove 50% male fertile plants from female lines, but some sources of GMS are being developed as a temporary maintainer to overcome this necessity. The third system is self-incompatibility (SI). One of the major problems of this system is the effort and cost involved in increasing the SI lines by, for example, bud pollination, controlled CO_2, spraying salt liquid.

Oil Content

Oil content in most cultivars of rapeseed is ~38–44%. It is controlled by multiple genes, also strongly influenced by the environment, particularly temperature, moisture stress, and soil nitrogen. To increase the oil content is a long breeding program. The general strategy for this goal is to employ a recurrent selection or selected progenies derived from higher oil content combinations. However, there is a negative correlation between oil content and protein content (which affects meal quality). Breeders must often choose a suitable index (oil + protein) to increase both of them.

Yellow seedcoat has been shown to be associated with low fiber content and therefore higher oil and protein content. The trait is more common in *B. rapa* and *B. juncea*, but is less common in *B. napus*. The inheritance of the trait depends on the species and sources of genes, but there is no general agreement. Recent work, using genes from other species in U's triangle, seems more useful.

Oil Quality

Oil quality is determined by its fatty acid composition. The nutritional and economic values are dependent on the content of each component in the oil. The goal in improving the oil quality is to reduce the terminal products in the fatty acid synthesis pathway, such as erucic and linolenic acids. Old rapeseed cultivars have a higher erucic acid content. The first low-erucic-acid genes were found in Liho, Germany. This foundation has led to the first low-erucic-acid rapeseed (LEAR) cultivars. Erucic acid content is determined by the embryo genotype, and is controlled by one gene in *B. rapa* and two in *B. napus* and *B. juncea*. Selection for low-erucic-acid content is always by transferring from an LEAR. On the other hand, high-erucic-acid rapeseed cultivars have some markets to supply. Linolenic acid reduces the oil storage time because of its three unsaturated bonds in the carbon chain. The selection for low linolenic acid content has not been easy, as the content does not vary much in the germplasm and it is a necessary product of photosynthesis. Even breeder can select low linolenic content lines from the mutations

induced by some chemicals and irradiations, and the cultivars do not have a higher yield potential than the conventional cultivars.

The fatty acid composition can be changed by reducing the content of saturated fatty acid and by increasing the content of polyunsaturated fatty acid, to regulate the ratio of linoleic and linolenic acids to be 2 : 1.

Meal Quality

Canola meal for feed use is recognized for its consistent quality and cost-effectiveness. The meal quality is defined by the glucosinolate content. The glucosinolate is a series of compounds that have a core structure (–S–C=N). The compounds hydrolyze (when the seed is crushed) to produce isothiocyanates, which reduce the amounts of meal that can be incorporated in livestock feed. Bronowski, a Polish cultivar, has been identified as having low glucosinolate content. The genetic analysis has shown that inheritance of the trait involves three pairs of recessive genes at least. The mother-plant genotype determines the glucosinolate level in the seed.

Breeding for low glucosinolate content is usually to transfer the trait by crossing between high and low glucosinolate level. The frequency of the plant with low glucosinolate is less than 2% in an F_2 population. There are a series of methods to analyze its content in seeds, such as the glucose test tape which is used for urine sugar analysis, near-infrared reflectance (NIR), high-performance liquid chromatograply (HPLC), etc. Recent research has indicated that the glucosinolate may be related to some diseases and pest resistances.

There are a series of unhealthy components in the meal, such as tannins, phenolic compounds, phytic acid, etc., which should be reduced.

Diseases and Pest Resistance

Stem canker (blackleg) is caused by *Leptosphaeria maculans*. It is an important disease of *B. napus* in most countries, except China. Different areas have different pathogen groups. Sources of the resistant genes have been found within the *B. napus* species from Europe and Australia, *B. juncea* and *B. sylvestris* (a wild form of *B. rapa*). The inheritance has different modes depending on the gene sources. Methods of screening genotypes of resistance have been developed using natural and artificial inoculations. The molecular markers related to some loci have been identified and applied to breeding programs.

Stem rot (*Sclerotinia*), the most important disease of rapeseed in central China, is also a major cause of crop loss in France, Germany, and other parts of Europe. The main agent is ascomycete *Sclerotinia sclerotiorum*. The wide range of the fungus hosts and failure to find gene sources of resistance in many species pose a difficult challenge for breeders. Infection mainly occurs because of the fungus entering the plant by senescing petals that have dropped onto leaves or in leaf axils as a medium for penetration by the ascospores. When the fungus invades the host, oxalic acid is released quickly, which causes necrosis. The breeders have two ways to control the disease: one is to develop apetalous cultivars to block this invaded route and another is to introduce a gene for oxalate oxidase by transformation.

There are many other diseases in rapeseed, such as white rust in *B. juncea* and *B. rapa* caused by *Albugo candida*, alternaria leaf and pod spot caused by *Alternaria brassicae*, light leaf spot caused by *Pryenopeziza brassicae*, white leaf spot caused by the ascomycete *Mycosphaerella capsellae*, club root caused by *Plasmodiophora brassicae,* and virus diseases. For some diseases, intraspecific crossing or genetic transformation may be the only recourse to incorporate resistance into susceptible species.

For the time being, insecticide will remain the basis of insect pest control in *Brassica* oilseed. The breeding for insect pest resistance has not advanced much. Recent work in biotechnogical methods of plant breeding may allow entomologists to design specific oilseed plants for resistance.

Lodging and Shattering Resistances

There are clear differences of lodging and shattering resistances between cultivars, but the inheritances of the traits are unknown. Breeders select the resistances by evaluating plot trials in the field. The sorts of the traits depend on the eye of the breeders and cannot be defined easily. The lodging resistance may be correlated to the flexibility of the stem and the height of the plant. Seed loss through shattering at harvest time is a problem in *B. napus* but less so in *B. rapa* and *B. juncea*. Attempts have been made to introduce resistant genes from other species but the inheritances are complex.

Application of Biotechnology

Biotechnology has a major impact in three areas. First, it is the application to tissue culture. In microspore culture, one derives a whole plant from the numerous immature microspores in anther by doubling the chromosome number with colchicine. The genotypes of all loci are completely homozygous. This method shortens the breeding time. Protoplasm fusion is applied to introduce some available genes

from other species related to *Brassicaceae*, such as restorer gene for ogura cytoplasm, disease-resistant genes, etc.

Second, it is genetic modification by plant transformation. There have been many great advances in *Brassica* species compared with most other major food crops, such as herbicide resistance, changes in fatty acid composition, pollination control genes (TA29 – barnase, TA29 + barstar), and disease and insect pest resistances.

Finally, it is molecular-assisted selection. Molecular markers can help breeders to select the genotype rather than the phenotype. The selection could be more effective.

Here, it is necessary to present that the model plant, *Arabidopsis*, is very close to the *Brassica* species in genome. All of the information out of *Arabidopsis* researches may be applied to canola improvement.

Conclusion

Breeding for the *Brassica* species has played an important role in the improvement of yield, quality, and resistance, and will continue to do so in the future. Breeders need to pay attention to the negative correlations between traits. For example, reducing the glucosinolate content might cause a decrease of the resistances to *Sclerotinia* and pest; increasing the oil content might decrease the yield; increasing the number per pod might decrease the seed weight and the number of pods. Breeders would use all available technologies to regulate all the traits and engineer them into a plant in order to enhance the crop productivity.

Introduction: The Three Species and Their Agro-Ecological Niches

This article introduces the three main *Brassica* oilseed species, and analyses the factors affecting their development and growth. A model approach is used to synthesize the information into a coherent whole, based on the way crops use solar radiation and other resources. This is then used as a framework to examine how the crop can be managed to efficiently produce oil and protein, by manipulating cultivar, sowing time, plant population, nutrition, water supply, and other inputs. Finally, the crop is considered in a wider farming-systems context.

Brassica oilseeds have been used as cooking oils in India, China, Japan, and less developed parts of Europe for centuries. Rapeseed oil has also been used as a lighting oil and as a lubricant in western Europe since about the fifteenth Century, but only as an edible oil there and in North America since the Second World War. By the 1960s, it was shown that erucic acid, the long-chain fatty acid characteristically found in *Brassica* sp., which gives the oil excellent lubrication properties, was implicated in heart disease in mammals as it could lead to hardening of the arteries. Pioneering work in Canada showed that erucic acid could be virtually eliminated by breeding, leading to the first low-erucic-acid varieties, Oro and Span (*B. napus* and *B. rapa*, respectively) by the late 1960s. At this time it was also shown that the glucosinolates, the mustard-type compounds found in the seed which restricted feeding of the meal (the seed residue after oil was extracted) to livestock, could also be reduced to a low level by breeding, initially using a Polish variety Bronowski.

"Canola" is a name coined in Canada for "double low" varieties containing specific seed quality characteristics: low erucic acid (less than 2%) and low glucosinolate levels (less than 30 μmol g^{-1} of meal). These quality traits are now available in all three species. The development of canola, with new food and industrial applications and a new "image," allowed the rapeseed industry to expand rapidly in western Canada, where it rivaled the wheat industry in size and complemented it in crop rotations by the 1990s.

The three main oilseed *Brassica* species are listed below, with the main growing environments. The first two species are available as either "winter" cultivars, with varying requirements for chilling over winter (vernalization) before they will flower, or as "spring" cultivars, which need little or no vernalization. Winter cultivars are normally sown in autumn or early winter, whereas spring-type cultivars are sown in spring in colder areas, or autumn/winter in milder climates, where their growth over winter and early flowering is not a disadvantage.

Brassica napus L. (Oilseed rape, or Rapeseed)

This species has the highest yield potential under favorable growing conditions, and has the widest adaptation. Winter cultivars form the main crop in Europe, where winters are mild enough to allow survival and slow growth. Spring-type cultivars are grown in western Canada from spring sowing, where winters are usually too cold to allow crop survival, and in Australia from autumn/winter sowing. In China and Japan, the crop is grown in winter, often in rotation with rice over summer, so early maturing cultivars are required. These usually have a moderate vernalization response as winters can be cold. Virtually all cultivars, however, will show some response to vernalization, although it may not be necessary to proceed to flower and may be substituted for by the effect of long days in spring/early summer.

Brassica rapa L. (Turnip Rape, Previously Also Known as *B. campestris*)

The most cold-hardy of the species, which tends to be cultivated on the northern fringes of the cropping belt in Europe, for example, in Scandinavia (winter and spring cultivars) and Canada (mainly spring cultivars), particularly in the Peace River district and in northern Alberta. The release of earlier-maturing, higher-yielding *B. napus* cultivars has resulted in contraction of *B. rapa* from about half the Canadian area to a much smaller proportion. Three ecotypes are also grown in India, brown sarson (the major area), yellow sarson, and toria.

Brassica juncea L. Czern and Coss. (Indian or Oriental Mustard)

Mustard is the species with the greatest tolerance of heat and drought. It has been grown extensively as an oilseed and condiment in India, and to a lesser extent in Canada, mainly as a condiment (brown mustard) in low rainfall areas in southern Alberta. The development of canola quality cultivars in Australia and Canada opens up the drier parts of the grain belt in both countries to larger-scale production as an oilseed, and allows diversification away from the existing very limited cereal/fallow systems.

The rapeseed/canola crop needs to be seen as one component of a farming system, being normally grown in rotation with other crops such as cereals and legumes. It is also often included as part of a mixed farming system, with livestock such as sheep and cattle grazing crop residues and sown pasture leys, or pigs and poultry being fed by-products such as canola meal once the oil is extracted from the seed. There are particular benefits to be gained from inclusion of rapeseed in these systems, to be covered below as "biological fumigation," as well as the general break crop effect on diseases, pests, and weeds of other crops.

Crop Development and Growth: A Model Framework for Crop Management

To understand how the crop responds to management of agronomic inputs such as choice of cultivar, seed rate, fertilizer, and sowing time, it is necessary to have

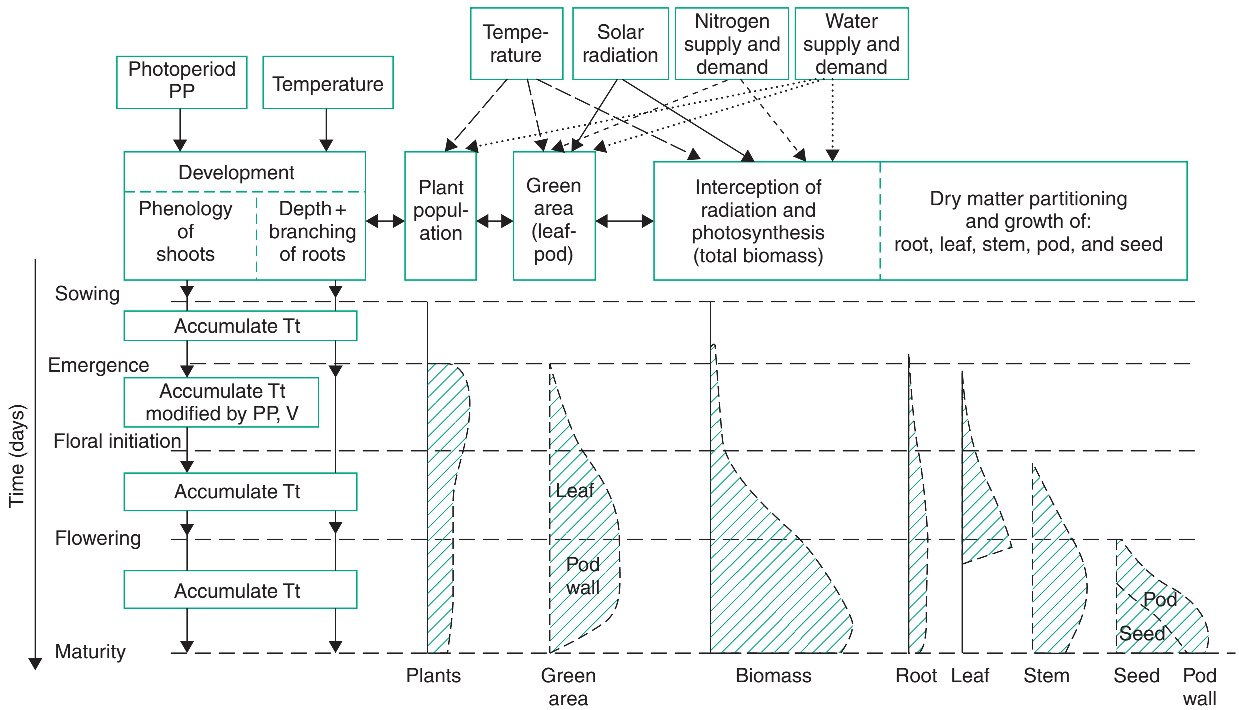

Figure 1 Diagrammatic representation of development and growth of canola (rapeseed), as used in APSIM model. Tt = thermal time, PP = photoperiod, V = vernalization. (Based in part on: Weir AH, Bragg PL, Porter JR, and Rayner JH (1984) A winter wheat crop simulation model without water or nutrient limitations. *Journal of Agricultural Science, Cambridge* 102: 371–382.)

a clear picture of how it develops through its life cycle and grows with respect to photosynthetic organs and weight of all components (i.e., grows). These two processes, development and growth, proceed in parallel to result in the final yield, but should be clearly distinguished because environmental factors affect them differently. An overview is shown as Figure 1.

Much research effort in Europe (particularly France and the Netherlands) and Australia has been devoted over recent years to modeling the development and growth of the rapeseed crop. The agricultural production systems simulator (APSIM) family of models in Australia has been extended to include rapeseed/canola (Figure 1), and will be used to show how the modeling approach has aided thinking about crop management in a farming-systems context. In developing a model, the characteristics of the crop have to be described quantitatively, posing questions that may or may not have been answered by previous research.

Crop Development in Relation to Environmental Factors

The timing of length of life cycle stages is critical in fitting cultivars to their intended environment. This includes adapting to overall length of growing season, minimizing the effect of stress times such as frost and drought, and synchronizing sensitive stages such as flowering and seed set with favorable conditions.

Development rate is largely governed by temperature, so time from sowing to seed germination and seedling emergence, and the rate of leaf production are proportional to temperature, up to ~20°C. They can be described by units of “thermal time,” or day-degrees (°C d) above a base, which can be assumed as 0°C for most purposes. Seed germination and plant emergence may take ~120°C d if soil moisture is adequate. Leaves on the mainstem are then produced about every 75°C d until the beginning of stem elongation (i.e., about every 4 days at an average 20°C), then every 20°C d until flowering. The number of leaves produced on the mainstem of a plant ranges from a minimum of ~6 on early maturing cultivars in the long days of the Canadian summer to over 30 in winter cultivars in Europe. Temperature also controls the rate of seed development, so different cultivars may require from 500°C d to 800°C d (Canada and Europe, respectively) from flowering to maturity. In Australia, most cultivars require 600–700°C d. This means that, for example, a single European winter cultivar may require 60–100 days from flowering to harvest, depending on whether it is a warm or a cool summer.

In addition to the basic positive effect of temperature on development rate, the progression towards flowering is also controlled by the vernalization response, as noted earlier on winter cultivars but also to a lesser extent on most others. Here, a period of time at low temperature (~2–7°C is most effective, with temperatures over 15°C having no effect) promotes initiation of the inflorescence at the growing apex, and cessation of production of leaf primordia. The apparently opposite effects of temperature on general development rate and on vernalization have been successfully included in the models. Photoperiod is the other major environmental control, with rapeseed cultivars usually responding to longer days from as soon as they have emerged. As photoperiod increases from ~11 to 16 h, duration of the period from plant emergence to floral initiation is reduced. Following initiation, there is a period of ~250°C d prior to flowering which is unaffected by daylength or vernalization.

Crop Growth in Relation to Environmental Factors

Good crop management can be thought of as a two-stage process: (1) the production of an efficient leaf canopy by flowering time, and (2) the efficient conversion of photosynthate into oil and protein during seed development. Agronomic management to achieve this will be the focus of a later section.

Leaf expansion as well as production is proportional to temperature, with favorable conditions during leaf initiation and cell division leading to potentially larger leaves. Final leaf size is also a function of position on the plant, progressively increasing in size to about fifth true "rosette" leaf, then declining during stem elongation until becoming quite small on the upper mainstem. Leaves then remain active on the plant for ~400–800°C d, so the size of the leaf canopy is determined by factors affecting production, expansion, and senescence of leaves. The leaf area index (LAI), or area of leaf per unit ground area, is a key to efficient interception of solar radiation and hence photosynthesis. Figure 2 shows that a canopy of LAI 3 will intercept ~85% of incoming radiation, with an extinction coefficient (k) for radiation of ~0.6 (the slope of the relationship between LAI and the log of the fraction of radiation intercepted, which also varies with leaf angle and shape). If LAI greatly exceeds 3, little further radiation is intercepted, resources are wasted, and the dense canopy may encourage diseases and pests. A target for managers could therefore be the achievement of 85% radiation interception (equivalent to near-full ground cover) by flowering time.

The leaf canopy will convert intercepted total solar radiation into aboveground biomass at 1–1.5 g MJ^{-1} (average ~1.2 g MJ^{-1}) radiation use efficiency (RUE), as in the example in Figure 3 for three cultivars

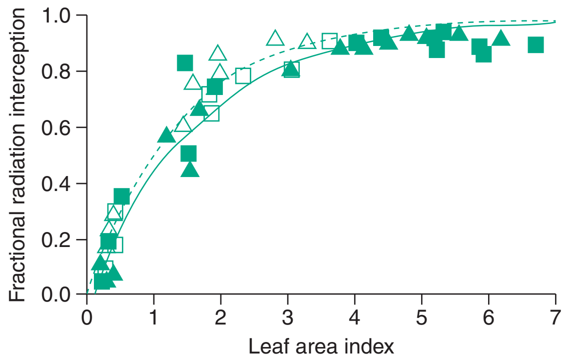

Figure 2 Fraction of solar radiation intercepted by green leaf area of canola crops at different stages of growth and levels of irrigation. Conventional cultivar indicated by square symbols, triazine tolerant cultivar by triangles, with fitted curves for extinction coefficient k of 0.58 and 0.72, respectively. Closed symbols indicate fully irrigated, open symbols partly irrigated. (Reproduced with permission from Robertson MJ, Holland JF, Cawley S, *et al.* (2002a) Growth and yield differences between triazine-tolerant and non-triazine-tolerant cultivars of canola. *Australian Journal of Agricultural Research* 53: 643–651. CSIRO Melbourne.)

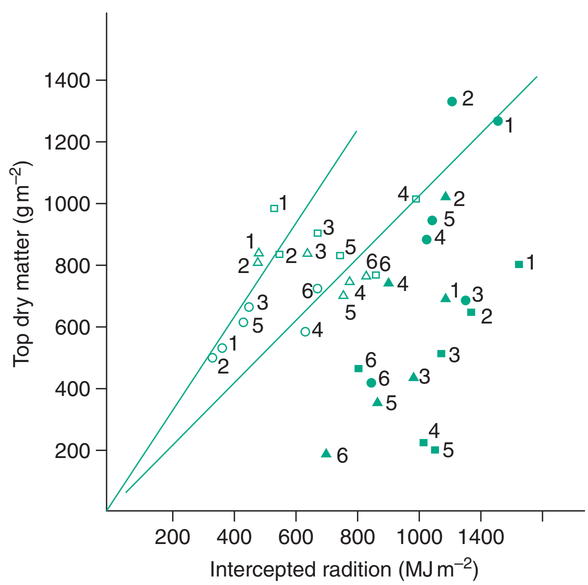

Figure 3 Relationship between the top dry matter (biomass) produced and amount of solar radiation intercepted by rapeseed crops between sowing and flowering (open symbols) and between flowering and harvest (closed symbols). Different symbols denote different cultivars, and numbers next to each symbol indicate order of sowing. Lines drawn indicate RUE of 1.0 and 1.5 g MJ^{-1}. (Reproduced with permission from Mendham NJ, Russell J, and Jarosz NK (1990) Response to sowing time of three contrasting Australian cultivars of oilseed rape (*Brassica napus*). *Journal of Agricultural Science, Cambridge* 114: 275–283. Cambridge University Press.)

sown on six dates from autumn until spring. RUE will vary, depending on exposure to stress factors such as drought, high temperature, and disease. In cultivars with tolerance to the triazine group of herbicides, altered photosynthetic metabolism leads to ~20% lower RUE. During flowering, the efficiency of all crops drops, due to reflection of radiation and shading of leaves and earlier-formed pods by the mass of yellow flowers at the top of the crop. Subsequently, during pod development a new green canopy is established, consisting mainly of green pods which, compared to leaves, have ~10% lower efficiency per unit green surface area. While the pods have an extinction coefficient similar to that of leaves, they have fewer stomata able to exchange carbon dioxide and water. They also have a lower nitrogen concentration than leaves, which may reduce efficiency. Green area index (GAI, total green surface area) is therefore more relevant than just LAI in estimating crop radiation interception and efficiency of its use. Figure 3 shows that the crops after flowering grew at RUE mainly below $1\,\mathrm{g\,MJ^{-1}}$, and in the case of some later sowings affected by higher temperatures, water stress, and pest damage, as low as $0.2\,\mathrm{g\,MJ^{-1}}$. A lower RUE during seed fill will also be a result of the biosynthetic cost of oil production compared to carbohydrates and proteins earlier in the growing cycle. Oils contain ~2.5 times as much energy as carbohydrates. This figure is discussed further below, in the section on sowing time.

Yield Components and the Efficient Conversion of Dry Matter to Oil Yield

Final oil yield can be thought of as a product of the yield components:

$$\begin{aligned}\text{Oil yield} = {} & \text{plants m}^{-2} \times \text{pods plant}^{-1} \\ & \times \text{seeds pod}^{-1} \times \text{mean seed weight} \\ & \times \text{oil seed content (\%)}\end{aligned}$$

This numerical approach on its own is of little value, but is useful if combined with a knowledge of when the different components are formed, the external factors affecting them, and internal competition for photosynthetic assimilate, nutrients, and water. Plant establishment (numbers and spatial distribution) and survival over winter form the first component. Flowering and pollination determines the potential number of both pods and seeds, with pollination not normally a limiting factor in the largely self-fertile *B. napus* and *B. juncea*. Seed set in cross-pollinated *B. rapa*, or in hybrid seed production in *B. napus*, may be dependent on good weather and the presence of bees or other pollinating insects.

The survival of a particular pod is largely determined during the first 2–3 weeks after pollination, when competitive pressures build up as the canopy of pods forms at the top of the crop. Numbers of pods per square meter are thus determined shortly after the end of flowering of the crop as a whole. For the remaining components, Figure 4 shows an example for a surviving pod. Abortion of seeds also occurs over the first 3 weeks, and can result in substantial losses of potential, from ~30 seeds per pod down to nil in an extreme case. This may be due to internal competition for resources if too many pods are formed, or external stress due to drought, low radiation levels, or frost. Significant seed growth does not begin until after ~3 weeks from seed set, once pod walls have reached near their full length and about half their final weight. Seed growth continues at an approximately linear rate until near-full size is reached. Buildup of oil content closely follows that of seed growth. There can be substantial compensation between yield components, for example, if seed abortion is particularly severe, remaining seeds can grow to a larger-than-normal size.

An illustration of an efficient crop canopy compared to an inefficient one after flowering is shown

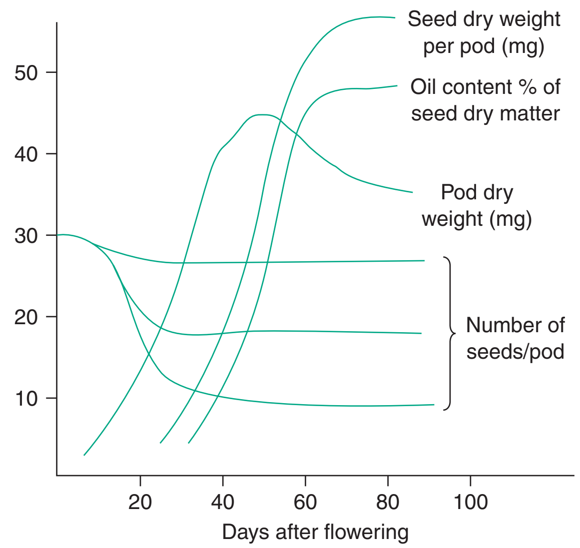

Figure 4 Example of formation of the yield components within a single pod, as a function of time after flowering. Three hypothetical levels of number of seeds per pod indicated, corresponding to high, medium, and low seed survival. (Based in part on Hocking PJ and Mason L (1993) Accumulation, distribution and redistribution of dry matter and mineral nutrients in fruits of canola (oilseed rape) and the effects of nitrogen fertilizer and windrowing. *Australian Journal of Agricultural Research* 44: 1377–1388. CSIRO Melbourne, with permission.)

as Figure 5. This is a "snapshot" of two canopies produced in different seasons, but with the same cultivar and similar management. One crop had 9500 pods m^{-2}, and the other 6000 pods m^{-2}. The figure shows the crop in 20 cm thick layers, on a typical day with 20 MJ m^{-2} incident solar radiation. In the "thick" canopy, radiation was mainly attenuated within the upper pod canopy, where there were many more aborted pods and seeds than within the "sparse" canopy. In the latter, radiation was spread more uniformly over the pod layer, with about half penetrating to the leaf layer below, allowing continued functioning. This is likely to have been a major contributor to the better seed survival.

Harvest index measured at maturity (seed yield as a proportion of total aboveground biomass) is a consequence of the balances between biomass accumulation before and during grain-filling, as well as the extent of translocation of stored dry matter from vegetative organs to grain. These processes will be affected by the timing and severity of stresses with respect to the stage of crop development. Harvest index in canola typically varies between 0.25 and 0.35 (lower than for cereals due to the energy cost of oil biosynthesis), although severe stresses at certain stages of development can lead to values lower than this range.

Seed oil content in canola is affected by cultivar attributes and the environmental factors of temperature, water stress, and N supply during seed development. As the last component formed, it is broadly correlated with harvest index (Figure 6a) and seed size (Figure 6c) as similar factors will affect each. It may not be strongly correlated with seed yield (Figure 6b), as the main factors affecting yield may be determined well before oil is being formed.

As in other oilseed crops, high temperature has been shown to lower oil content and alter composition of fatty acids. Oil content declines by ~1.2% for each rise in mean air temperature of 1°C during grain filling (Figure 6d). Water stress after flowering also can have a severe effect on oil content. Increasing the N supply to the crop almost always reduces the oil content of the seed, because a better supply of N increases the formation of N-containing protein precursors so that protein formation competes more strongly for photosynthates. As a result, less photosynthates are available for fat synthesis. In a review of winter rapeseed experiments the depression of oil content was in the range of 0.8–2% of oil content per 100 kg ha^{-1} of N applied. In the spring rapeseed experiments surveyed the depression was less, in the range of 0.6–1.2% of oil per 100 kgN ha^{-1} applied. There was little evidence that late N application, which might be expected to enhance N supply to the seed rather than the vegetative components of the crop, has any particularly depressive effect on oil content. In the field, cultivar maturity will tend to be confounded

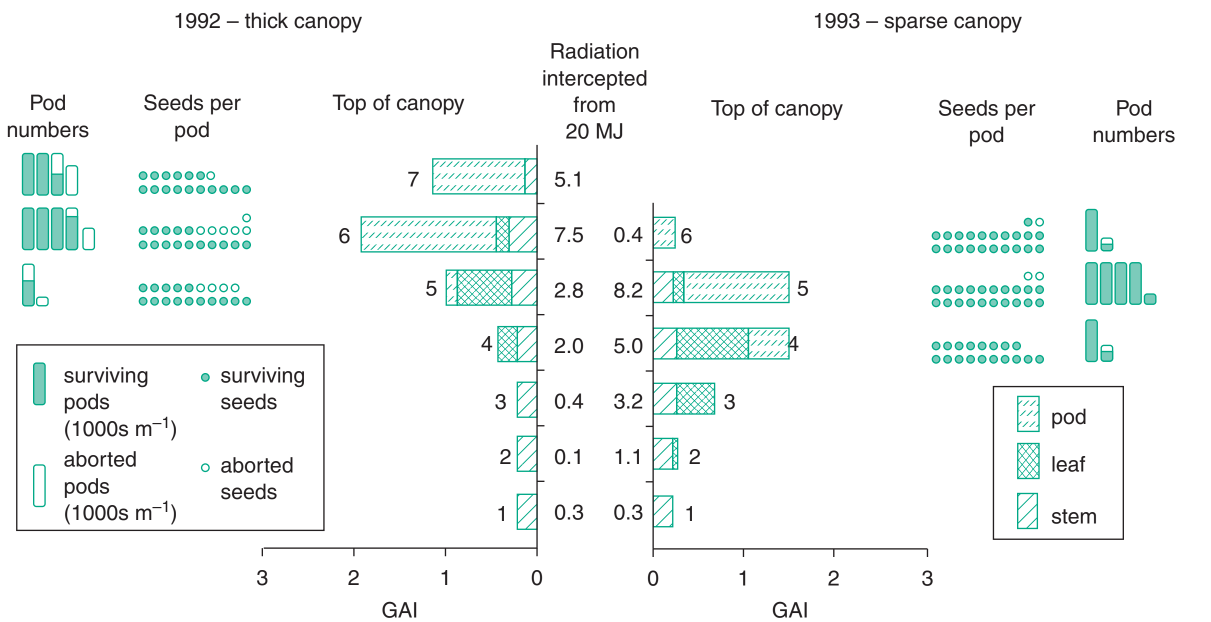

Figure 5 Diagrammatic representation of the canopies of two rapeseed crops in 20 cm layers, showing the distribution and nature of the amount of radiation intercepted, the intercepting green surface area, and the fate of pods and seeds. (Reproduced with permission from McWilliam SC, Stafford JA, Scott RK, Norton G, Stokes DT, and Sylvester-Bradley R (1995) The relationship between canopy structure and yield in oilseed rape. In: Murphy D (ed.) *Proceedings of the 9th International Rapeseed Congress*, pp. 491–493. Cambridge, UK: GCIRC Paris.)

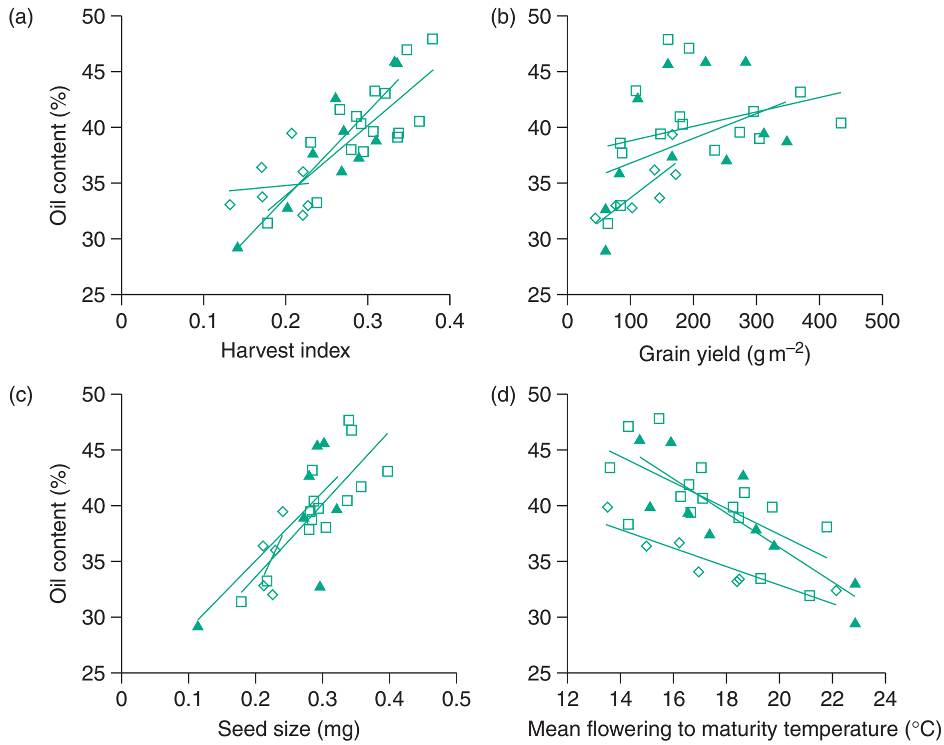

Figure 6 The relationship between seed oil content and (a) harvest index, (b) grain yield, (c) mean seed size, and (d) mean temperature from flowering to maturity. Crops of two cultivars of canola indicated by square and triangle symbols, and one of Indian mustard (*B. juncea*) indicated by diamond symbols, with regression lines fitted to each. (Unpublished data MJ Robertson.)

with temperature and end-of-season drought. However, even after allowing for flowering time, there are still cultivar differences in oil content. The few studies exploring the issue of genotype–environment interaction for oil content in canola have shown only small effects, indicating that oil content is largely a characteristic of the genotype.

End-of-season drought is likely to limit oil content as well as yield, particularly in regions where autumn or winter sowing is normal. Spring sowing, however, as practiced in short-season cool environments like western Canada can lead to different problems as low autumn temperatures, and particularly frosts, curtail oil buildup and crop ripening. This may also lead to poorer-quality oil as unsaturated fatty acid synthesis may be halted, and high levels of chlorophyll may remain in the seed, particularly on later flowering branches. This leads to downgrading of the seed and greater oil-refining costs.

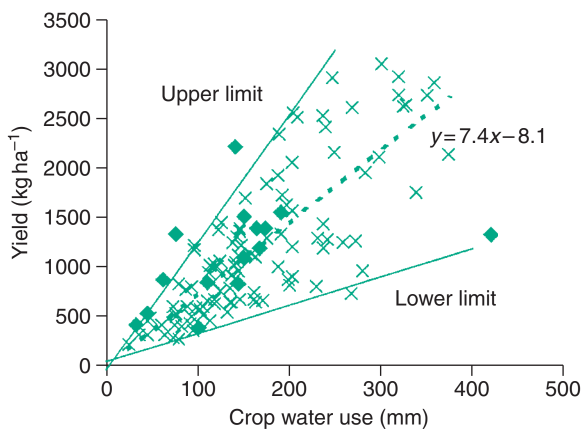

Figure 7 Water-use efficiency of measured (diamond symbols) and simulated (crosses) crops. Upper and lower limits of 13 kg ha mm^{-1} and 3 kg ha mm^{-1} indicated by solid lines, with the fitted average line showing efficiency of 7.4 kg ha mm^{-1}. (From Cocks B, Robertson MJ, and Cawley S (2001) Water extraction and water-use efficiency of canola in the north. In: Marcroft SJ (ed.) *Proceedings of the 12th Australian Research Assembly on Brassicas*, pp. 203–207. Australia: Geelong.)

Water-Use Efficiency

An alternative approach to the radiation and temperature driven model (as outlined in Figure 1, with example in Figure 3) is a model widely used in Australia based on water-use efficiency (Figure 7). This is based on the principle of the known strong correlation between photosynthesis and transpiration, and hence between biomass production and water use. In water-limited environments, healthy crops will produce seed at up to ~13 kg ha^{-1} mm^{-1} of available

water, including stored soil water before sowing, and effective rainfall during crop growth. Lower efficiency figures (down to $3\,kg\,ha^{-1}\,mm^{-1}$) may indicate that other factors are limiting, e.g., nutrition, drainage, or frost. The efficiency will, however, also vary with evaporative demand – a hot or windy season will result in lower efficiency. It will also depend on whether the rainfall was received at a critical time, such as just after flowering, or too late in seed growth to affect yield. In spite of these constraints, this model has been useful for researchers and farmers to compare their crops, and as an extension tool.

Crop Management

The main goal in early crop management is to produce a canopy with near-full ground cover of healthy leaves by flowering time, with efficient use of resources. There is usually no advantage in excessive leaf or stem production.

Plant Population and Arrangement

The crop generally shows very little response to seed rate over a range of plant populations from ~30 to $100\,plants\,m^{-2}$. Seed rates to produce these populations may vary from 3 to $12\,kg\,ha^{-1}$, with resulting seed yields within 10% of the maximum. This is because the plants are "plastic," able (within limits) to keep producing leaves, and later branches and flowers, to occupy the site fully. Lower densities may therefore give prolonged leaf persistence, extended flowering and delayed maturity. While narrow (15 cm or less) row spacings will give quicker ground cover, hence radiation interception and weed suppression, wide (20 cm or more) spacings produce similar results, and may be desirable in direct-drilling situations for trash clearance.

Where crop establishment has been poor and crops are patchy, worthwhile yields (over 50% of that at optimum density) may still be obtained down to $10-20\,plants\,m^{-2}$, provided the season is favorable to allow the compensatory growth. Very low density crops may be subject to more pest damage and weed invasion.

Crop Establishment

While grower guides such as the "Canadian Canola Growers' Manual" may suggest that "seed must be placed into a firm, moist, warm, aerated, well-structured seed bed for rapid germination and seedling growth," one or more of these requirements are often compromised in practice. Even though seeds are small (2–5 mg), their high oil content does give substantial energy reserves and hence ability to overcome some constraints. The crop tolerates a wide range of pH (~5.5–8, measured in water), and will emerge well from sowing depths of 5–30 mm. Sowing up to 50 mm may be required in some seasons to reach moisture, but emergence and early vigor may be reduced. Residues from previous crops on the soil surface may also impede establishment, particularly in direct-drilled situations, so burning, baling, or incorporation may be desirable. The trade-off with the benefits of trash retention needs to be assessed in each situation. Very low soil temperatures (5°C or less) may reduce establishment as well as delay it, and there may be an advantage from using *B. rapa* or other more cold-tolerant types in this situation. The insulating effect of stubble and trash may also exacerbate frost damage on young seedlings, by preventing heat flow from the soil.

Differences in seed germination rate and vigor have been found between different seed lots of the same cultivar, and use of high quality seed will assist in overcoming the above constraints. Large seed size on its own does not necessarily mean greater vigor, but will usually give initially larger seedlings. Greater seed weight for the same size (i.e., density) may be a better indicator of vigor.

Sowing Time

The guiding principle is to sow an adapted variety in time for it to reach near-full radiation interception by flowering, which needs to be late enough in spring to avoid frost damage and other unfavorable weather during pollination and seed set. There also needs to be enough growing season left after that to achieve grain fill and an economic yield before constraints of drought (e.g., in Australia) or frost (e.g., in Canada) intervene. The use of a phenology model as part of an overall model such as APSIM will assist prediction of optimum sowing dates. Delayed sowing, whether in autumn or spring, will in most environments result in progressively lower yield (e.g., 4% loss in yield for each week's delayed sowing in widely separated areas of Australia). Delays of a month in sowing may result in only a few days delay in flowering (driven more by responses to photoperiod and vernalization), hence shortening the period for leaf expansion and growth. While most crop species respond in a similar way, the specific morphological change in rapeseed from the leaf canopy to the mass of flowers (reflecting and absorbing radiation) and then pods at the top of the canopy puts a further restriction on vegetative growth, as leaves are largely shaded out during flowering and early pod growth.

For the experiment summarized in Figure 3 earlier, where crops were sown from mid-autumn through

to mid-spring, the highest yields were obtained from the second sowings (late autumn, points labeled 2 in figure). Good early growth, at high efficiency of radiation use, $\sim$800 g m^{-2} top dry matter by flowering was followed by a long period for seed growth at moderate efficiency to produce over 500 g m^{-2} seed yield (equivalent to 5 t ha^{-1}). Some later (spring) sowings produced more dry matter before flowering at higher temperatures, but then had greatly reduced post-flowering growth and yield, to as low as 100 g m^{-2} from the latest spring sowing of the latest flowering cultivar. The first sowing produced lower yields than the second sowing, even though plants were taller and similar biomass was produced.

Earlier sowing than for the optimum timing as described above may be practiced for other reasons, e.g., in Europe to ensure good growth before winter so that crops can resist freezing, waterlogging, or bird damage. This may then lead to excessive growth in spring, very large numbers of flowers and pods, and an inefficient canopy, as in Figure 5. A low harvest index may result, with only moderate seed yields on a large biomass. Later sowings may give a higher yield, on sparser but more efficient canopies of pods. Breeding varieties with more restrained flowering, absence of flower petals (apetalous) and more efficient pod arrangement has been suggested to help widen the "sowing window."

Nutrition

Nitrogen is usually the most important nutrient to consider, due to its role in protein synthesis. This is of particular relevance for leaf expansion and chlorophyll content, hence radiation interception and efficiency of its use. Requirements are site- and season-specific, but $\sim$50–70 kg of N are required per ton of seed produced, to be met from soil or applied N. Guidelines are available for soil and plant analysis to achieve optimum yield without wasting resources, as shown in Figure 8 for leaf petioles, one of the most sensitive plant parts. The concentration of N required to achieve high seed yield falls as the crop proceeds through development. Most of the required N is taken up by the crop before flowering, with later distribution from leaves and stems to pods and seeds. In Europe, with a cold wet winter, there is no advantage in large autumn applications. These may be either leached into groundwater, or be taken up to produce excessive soft growth, resulting in winter kill. Application at the late vegetative to early stem extension stages has generally been shown to be of greatest benefit. In Australia or Canada, it may be more practical to include some either at sowing, e.g., with P in diammonium phosphate, or incorporated before sowing as anhydrous ammonia. Excessive N may result in too much leaf and stem growth, lodging, and high protein/low oil levels in the seeds as noted above.

Phosphorus and potassium requirements of rapeseed are similar to that of other crops, with nearly 12 and 20 kg, respectively, being removed per ton of seed. Sulfur is of particular interest, with deficiencies showing up in many countries as industrial air pollution is reduced (particularly in Europe), and high analysis fertilizers without sulfur are increasingly

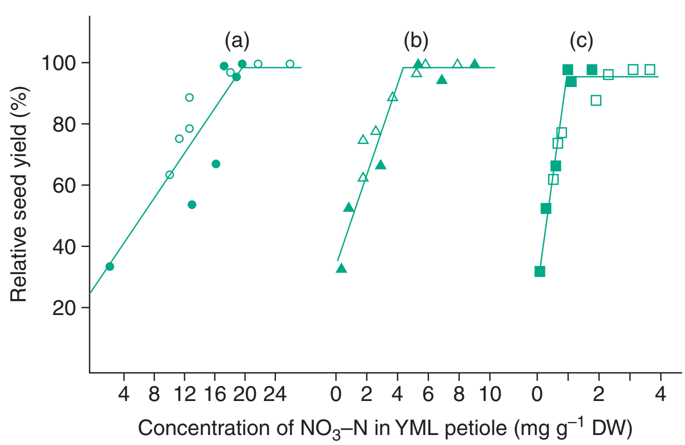

Figure 8 Relationships between nitrate–N in dried petioles of the youngest mature leaf (YML) of canola at three stages of development: (a) 5–6 leaf rosette, (b) flower buds visible, and (c) start of flowering, and relative seed yield expressed as a percentage of the best treatment at each of two sites. CSIRO Melbourne.)

being used. With ~10 kg required per ton of seed, plant tests can be used up to the beginning of stem elongation to decide whether to apply more. A deficiency shows up as characteristic pale, stunted, cup-shaped leaves (it is essential in chlorophyll formation and photosynthesis), creamy-colored flowers, and very poor pod development. Excessive S may contribute to high glucosinolate levels, as it is required for their formation. With the micronutrients, rapeseed (like other Brassicas) may benefit from molybdenum, boron, manganese, and zinc, although manganese toxicity may be a problem on acid soils.

Water Supply

While there is usually a good relationship between biomass production and transpiration, yields of seed, as in Figure 7, may be more influenced by water supply at critical stages. In most cropping areas and seasons, water supply through winter and early spring is adequate to allow crops to reach near-full ground cover. Assuming this, the next critical stage is at and just after flowering, when pod and seed numbers are being determined, and abortion most likely. Management of stored soil water from before sowing onwards can optimize the water supply at this critical time, by reducing losses through previous land management, soil cultivation, weeds, or excess crop growth. Irrigation, if available, is likely to have the greatest effect at or just before the critical time. Subsequently, water supply for grain fill and oil buildup is important, but unless there is a premium for large seeds and high oil content, mild water stress may not affect yield and profitability greatly. Irrigation or rainfall from flowering onward may also encourage disease, e.g., *Sclerotinia*, which thrives in flower petals shed and then lodged in leaf or stem axils lower in the crop. This has been a particular problem in Canada, but is also now becoming apparent elsewhere.

The greater tolerance of *B. juncea* to water stress appears to be due to osmoregulation maintaining turgor during the critical time for seed abortion, and hence resulting in up to 50% greater water-use efficiency than *B. napus*.

Crop Height and Plant Growth Regulators

Management should generally be geared to achieving modest crop height as part of an efficient crop canopy, through choice of cultivar, sowing time, N nutrition, water supply etc. as discussed above. Where height is likely to be excessive and leads to lodging, disease, and harvest difficulties, plant growth regulators have been tried, as in cereals, at least as an interim measure. Yields are not generally improved in the absence of lodging, and may be decreased by growth regulator application, so the economics of use are doubtful.

Harvesting

With an indeterminate inflorescence structure and lengthy flowering, pods and seeds on each plant ripen over an extended period, and in a field there may be considerable variation between plants in maturity time. The absence of good resistance to pod shattering in the main canola/rapeseed types therefore means that substantial losses can occur. Swathing at near physiological maturity (seeds turning black, moisture content ~15%) is therefore carried out on all but the lowest yield potential crops (less than ~$0.8\ \mathrm{t\,ha^{-1}}$). If swathed too early, lower yield and oil content may follow, and chlorophyll content of seeds may be too high. Dessication using herbicides is an alternative but is not widely used. *B. juncea* does not need to be swathed as it has better resistance to pod shatter.

Canola/Rapeseed in Farming Systems

Weed Management

The crop generally fits well into farming systems, as a vigorous broad-leaved break crop. This gives the opportunity to control weeds and crop volunteers built up in previous cereal crops, by a combination of cultivation, competition, and selective herbicide use. If livestock are available on the farm, they can have an important role in cleaning up crop residues and weeds, and grazing pasture leys in rotation. While weed control is not normally a major problem in canola, the use of such integrated weed management systems is supplementing and extending the value of the commonly used herbicides. Resistance in the weed populations has been found to most of these chemicals, and the brassicaceous weeds such as wild radish (*Raphanus raphanistrum*), wild mustard (*Sinapis arvensis*), and wild turnip (*B. tournefortii*) present a particular challenge, being closely related to the crop. In Australia and Canada, triazine-tolerant canola cultivars have been extensively used, but their lower photosynthetic efficiency reduces competitive ability against weeds, as well as growth and yield. Newer herbicide-tolerant cultivars, whether produced by genetic engineering or conventional breeding, offer some advantages. The risks of herbicide-tolerant weeds, developing either naturally or by introgression from the tolerant crop, need to be assessed and suitable strategies implemented. While introgression into the above brassicaceous weeds is not likely, wild *B. rapa* may be more susceptible.

Biofumigation and Other Benefits

There are specific advantages of the Brassica oilseeds as break crops, supplementing their value as non-hosts, to control some soil-borne diseases such as take-all of cereals (*Gaeumannomyces graminis*), and some invertebrate pests such as nematodes. This is due to the content of glucosinolates in Brassica crop residues including roots that break down in the soil to form biocidal compounds, in particular isothiocyanates. Yields of cereal crops following canola are therefore often increased more than the non-host benefit of a break crop would suggest. There are opportunities to increase the level of the more highly biocidal compounds in roots by breeding, and also to maximize the effects through crop management. There are, however, concerns about the biocidal effects on beneficial organisms, such as *Rhizobia* bacteria for future legume inoculation, and vesicular–arbuscular mycorrhizal fungi, which aid some crops (but not Brassicas) in uptake of phosphorus and other nutrients.

Canola in Australia has also been observed to have beneficial effects on soil structure, with the long taproot helping to break up subsoil compaction and hard pans resulting from cultivation. Direct-drilled cereals may therefore be more successful following canola than other crops.

Harvest, Transport, and Storage

J J Mayko, Canola Council of Canada, Mundare, AB, Canada

Introduction

Canola is a small-seeded crop, but the principles used in the harvest, transport, and storage of this crop are similar to those used for many other small-seeded grain and oilseed crops. Various factors during harvest and handling process may have to be altered or modified to accommodate this crop. This article summarizes many of these factors and discusses methods used in the successful handling of this crop.

Harvesting Methods

As a high-yield canola crop approaches maturity, it may ripen very quickly. Gauging the correct time to harvest calls for more care and adjustments than with cereals. Canola can be harvested with the same swather and combine equipment as cereal crops, although the crops are quite different. Canola is often tall and branchy, with thick spongy stems. Swathers and combines must be properly operated and adjusted to facilitate a smooth flow of crop material through the machines while minimizing seed losses. With a few basic adjustments to most modern small-grain harvesting equipment, harvesting of canola is successful.

Canola can be harvested either by direct combining or by swathing and combining, depending upon the species and the growing conditions. The decision on which harvesting method is appropriate is dependent on a number of factors, including which species of canola is grown. *Brassica rapa* varieties are much more tolerant to pod shatter and drop than *Brassica napus* varieties and can therefore usually be left for straight cutting, if preferred. *Brassica napus* varieties can be direct cut as long as crop conditions are such that the crop is well knitted; that is where the crop canopy is thick enough that the branches are well knitted together, and therefore are much less prone to damage from pod shatter or drop from windy conditions.

When to Swath

Swathing at the optimum stage of ripening reduces green seed problems and seed losses, and ensures the quality required for top grades. To determine when a field of canola is ready to swath, plants from different parts of the field must be examined. The stage of maturity in an evenly maturing field will vary from plant to plant and from area to area within the field. Inspections every 2–3 days should begin when there is some seed color change in the first formed pods on the bottom of the main stem.

The color of the seed is more important than the overall color of the field in determining the stage of maturity. The best time to swath for optimum seed yield and quality is when all the seeds contain ~30–35% moisture. Examine only those pods on the main stem, except in conditions where the plant density is sparse, and more secondary branching has taken place. Seeds in pods on the bottom third of the main stem were formed earlier and will turn color much sooner than seeds in the pods of the top third of the plant. When the overall moisture content of seed from the total plant averages 30–35%, ~30–40% of the seeds in pods on the main stem only will have changed color or have started to change color. Seeds with only small patches of color should be counted as color changed. Most of the seeds that have changed color will be from the bottom third of the stem in *B. napus* varieties, whereas in *B. rapa* varieties some seed color change will also have occurred in the middle and upper pods. When seeds in

the bottom pods turn color, seeds in the top, last-formed pods are filled or nearly filled.

Most of the seeds will be firm, and roll, as opposed to break, when pressed between the forefinger and thumb. At this point, seed yield and quality are usually optimized.

Although the optimum time to swath canola is when 30–40% of the seed on the main stem has changed color, swathing should usually begin before the crop reaches the optimum color change stage. This is particularly important if one is growing large acreages of similar maturing canola. If the crop is left until the optimum stage before starting to swath, some of the crop will be too ripe by the time swathing is finished. Swathing earlier rather than later reduces risk for factors such as frost or diseases, e.g., blackleg, alternaria, and sclerotinia, if present. One or two days advantage may be critical in the fall when weather conditions can be unfavorable in a very short space of time. Swathing before 10% seed color change in any situation is not recommended unless the crop was seeded so late that it has not begun to reach seed color change before imminent frost. In that case, the canola can be swathed in order to salvage as much yield as possible before frost damage.

Work conducted in canola production centers across the Canadian prairies over 25 site years, for 1990–94, confirms that earlier swathing of *B. napus* canola (at 20% seed color change) can be an acceptable practice which causes minimal loss in yield and oil content (Table 1). The trials were conducted under field-scale conditions using standard farm equipment.

As *B. napus* canola has a narrower range in development time (due to less branching and podding) than *B. rapa* canola, it is possible to swath *B. napus* canola earlier without yield loss due to immature seed. This range in development time is affected by any factor that influences branching and podding. For example, a dense stand of canola branches less and, therefore, has a narrower range in development and can be swathed earlier. However, a light stand tends to branch more profusely and has a wider range in development. It may be advantageous to delay swathing a light crop to the higher end of the seed color change recommendation.

Swathing late, when seed moisture content is much lower (~80% seed color change), will result in fluffy windrows susceptible to blowing and increased shattering. To reduce shattering losses, over-ripe fields should be swathed when humidity is high, such as after a rain, after heavy dew, or at night.

It is difficult to determine when to swath unevenly maturing fields. Uneven maturity is usually the result of uneven spring germination where two or more flushes of germination have occurred. Determine which of the different stages of maturing plants is the majority. Swathing should occur as soon as some color change is visible on bottom pods of the main stem toward on the end of the major stages on the field.

Table 1 Effect of time of swathing on *B. napus* canola yield, oil, and protein in western Canada

% Seed color change	*Location years*	*Yield (%)*	*Oil content (%) @ 8.5% moisture*	*Protein content (%) @ 8.5% moisture*
0–10	25	90	40.8	20.7
10–20	25	96	41.5	21.7
20–30	25	100	42.2	21.6
30–40	25	100	42.8	21.6

Swathing Operation

The swather should be run just low enough to get all the seed pods, leaving the maximum amount of stubble in which to anchor the windrow and ensure adequate air circulation through the windrow. Such windrows tend to settle into the stubble and escape wind damage. This also minimizes the amount of material that must be handled by the swather and the combine.

The average crop of canola is handled quite readily with most swathers. However, stands that are exceptionally tall (1.5–2 m), thick, or lodged and tangled, make it difficult to lay an unbunched windrow. The windrow must flow smoothly through the swather without bunching. Bunching leads to uneven drying and combining problems. A large throat opening is important, particularly for wider swathers, to ensure that the swath will be of a size and shape that will dry and cure properly.

The swather should have good reel and table adjustments so that the crop can be cut as high as practical without losing any pods or causing shelling or bunching windrows. The reels should be set as high and as far forward as possible. Reel speed should be set to correspond with the forward speed of the swather. This speed will lay the cut material gently back on the table to avoid shelling. Table dividers, which are long and gently sloping, are generally less prone to blockages than short, abrupt types. When the crop is tall, tangled, and lodged, or laid across the seeded rows, divider blockages are almost inevitable unless special vertical cutter bars or power blades

are fitted on the swather. These can cause minor loss of pods and whole seed tops, but they prevent stops and bunching.

In areas where light fluffy windrows could be lifted and blown by the wind, a light roller pulled behind the swather will help anchor the windrow in the stubble. The roller should be set so that it just anchors the windrow into the stubble without shelling any ripe pods. Excessive rolling will produce a windrow that is too compact to dry quickly and difficult to pick up without shelling the canola.

Table 2 Effect of swathing vs. straight combining canola in western Canada on yield, oil, and protein

Treatment	*Location years*	*Yield (%)*	*Oil content (%) @ 8.5% moisture*	*Protein content (%) @ 8.5% moisture*
B. rapa (S)[a]	24	100	40.4	20.3
B. rapa (DC)	24	99	40.6	20.3
B. napus (S)	28	100	42.8	20.1
B. napus (DC)	28	89	43.5	19.9

[a] S = swathing; DC = straight combine.

Chemical Desiccation and Pod Sealants

The use of a chemical desiccant, which kills the green growth of pods, stems, and leaves, can result in a more uniformly ripened crop. This may allow earlier combining. A crop must be desiccated at the proper stage to achieve the best yield and seed quality. A desiccant should not be applied when the crop is immature or past the recommended stage of maturity. Desiccation may reduce the incidence of pod shattering and seed loss making it a possible alternative to swathing. However, the costs of the desiccant and its application must be taken into consideration.

When seed is mature but before pods become dry and split, pod sealants will slow pod dry-down and prevent the movement of moisture into and out of the pod, reducing shatter losses. Combine timing is crucial for minimizing shatter losses as the sealant efficacy diminishes with time and from repeated rains. Sealants slow crop dry-down and harvest by 5–14 days. This could be a concern in shorter season growing areas.

Combining Canola

Combining should begin when the seed is mature, fully color changed with no green seeds, and of a moisture content of less than 10% unless a drier is being used.

Canola crops which have been desiccated, or that are uniformly mature and free of green weeds, may be straight-combined without swathing. Work at canola production centres in western Canada has shown that most varieties of *B. raga* canola lend themselves well to straight combining. Straight-cutting of *B. napus* canola should only be attempted if crop conditions are favorable where crop growth is relatively heavy, with subsequent lodging, and where the risk of crop canopy movement from wind is low, and where the crop has low levels of disease (Table 2).

One of the main problems in straight combining in tall canola crops is ensuring freedom from blockages at the dividers and other table components so as to maintain a smooth crop flow into and through the combine. Again, long dividers or vertical power dividers can be effective in preventing crop blockages. To minimize shatter losses, the reel should be set well back and as high as possible to act as a precaution against stems falling forward. Reel speed must be matched carefully to forward speed to minimize seed shatter. Shatter losses can be reduced by combining a ripe crop when the pods are still damp from rain or dew, provided the moisture level of the seed does not exceed the safe storage level.

Canola in the windrow is ready to pick up and thresh when the seed temperature and moisture content have dropped to a safe storage level and most seeds are mature with no green color. While it is better to start on the early side for swathing, the same does not necessarily hold for combining. Hot or windy weather at, or after, swathing can cause canola seed to be at the appropriate moisture content for combining before it has cured and cleared the green chlorophyll. This occurs because the plant dries up before sufficient moisture can move into the seed to finish curing it. Canola requires at least 20% moisture in the seed for the maturing process to take place and eliminate the green seed color. It is important to check both moisture content and green seed count before starting to combine. Delaying combining can help clear the green color particularly if the swath sits through several heavy dews or light showers. If there are some green seeds, a few more days in the windrow may be all that is needed. Green seeds may ripen in the windrow but they do not cure significantly once they are combined. Before combining, a crush strip is used to ensure that the seeds are not green inside. A small percentage of seeds with green meat will reduce the grade. If wide swathers are used on tall, heavy crops, the result is very large windrows, which take a longer time to cure, especially at the center of the windrow. Bunching in the windrows also may contribute to a green seed problem as the crop dries out and cures unevenly.

Combine Checkout and Adjustment

Before combining, the combine should be checked over completely to ensure that it is in a good mechanical condition. Any holes through which the small seed can escape should be covered and plugged. Besides plugging all leaks it is important to keep the rest of the combine in good mechanical condition. Worn or loose components such as feeder conveyors, internal conveyors, and elevators are sources of seed cracking. The first setting of any combine – including threshing cylinder or rotor speeds, cleaning fan speeds, and cleaning sieve settings – should be set to the specifications in the operator's manual.

To minimize front-end seed losses on a combine equipped with a pickup, pickup speed and forward travel speed should be equal so that the windrow will be gently lifted without tearing or pushing.

Threshing cylinder or rotor speed will depend on crop conditions. Speeds set at about one-half to two-thirds of that used for cereals can often be used for canola. Speed reduction is important to prevent overthreshing of the pods and stems and overloading the cleaning sieves. Cracked canola is caused by impact when the cylinder speed is too fast. A speed that is too slow reduces the capacity of the combine. The cylinder speed should be maintained at a level where the amounts of cracked seeds are acceptable.

Once the cylinder speed has been set, concave clearance should be set as wide as possible to give a good threshing the first time through. The stems and pods should be broken no more than necessary and unthreshed pods should be kept to a minimum. This will reduce overloading of the sieves and allow seed separation without excessive dockage or load on the return conveyor.

For efficient threshing and cleaning, the combine should be operated as near as possible to its recommended capacity. Increasing the forward speed of the combine will increase the straw and chaff feed rate to a point where seed losses may increase dramatically. Too high a feed rate will exceed the capacity of the separating and cleaning components.

The proper adjustment of the fan and sieves for cleaning action is important since canola seeds are light and can easily be blown out of the combine or remain mixed with the chaff. Unlike the cleaning action for cereals, the cleaning action for canola should depend more on a shaking separation and less on a wind separation. While it is necessary to reduce the fan speed, enough wind must be used to maintain a "live" sieve. Air should be directed as uniformly as possible under the entire length of the sieve to keep the sieve "alive;" otherwise, stems, pods, and canola will move over the sieves in a mat and losses will be extremely high. The top sieve or chaffer should be opened enough for good separation (1/4 to 1/3 open, or 6–10 mm). This will keep the seed from going over the top and out the back. Air should lift the chaff on the sieve with a shaking action conveying the material along. The chaffer extension should be raised slightly (5–10°) at the rear and be open sufficiently to allow unthreshed pods through to the return. A chaffer opening that is too narrow, coupled with insufficient wind, will result in high seed losses. If the air blast is too fast (high fan speed), canola will be blown out with the chaff. Starting with a low fan speed and gradually increasing it until separation of chaff and seeds occurs, with no canola being blown over the chaffer sieve, is advisable.

The lower sieve should be adjusted depending on the sample in the hopper. Usually a setting of 3–6 mm will be sufficient for the lower sieve. If too much trash is in the grain hopper, the sieves are likely open too much. If the sample is perfectly clean, it means that canola may be going back to the return conveyor so that sieves should be opened slightly. Excessive returns can result in crackage of the seed. If the returns are too high, there may not be enough wind, the top sieve may be open too much, or the cylinder (rotor)-concave is overthreshing.

Since high losses are possible where combines are incorrectly operated or adjusted, the operator must make frequent checks and readjustments. Changing conditions during the day will change combine performance. Regular stops are suggested to check for losses and make adjustments in the field. A grain loss monitor aids in the detection of losses and a function monitor reports any problems in mechanical operation. Monitors must be installed correctly, calibrated properly, and handled carefully if they are to give reliable service.

Handling and Transport of Canola

Grain handling and transport systems are similar to those of cereals and other small grains and are designed to suit the needs of a particular farm, not for any special requirements associated with handling canola. Therefore, most transport and conveying equipment that is successfully used with small grain cereals can be used with canola. During transportation, all cracks in trucks and other equipment must be sealed with duct tape or caulking to prevent leakage and tightly covered to prevent canola seeds being blown away. Augers should operate at full capacity to prevent the seeds from flowing back down the tube and belt conveyors should be enclosed in a trough to

keep the seeds from running off-line. Kernel damage during handling is usually not a problem unless below 7% moisture content.

Storage of Canola

The main functions of grain storage structures are:

- protect the grain from damage due to moisture, heating, and insects;
- prevent losses due to leakage, rodents, and livestock; and
- provide reasonable convenience for handling or inspecting grain.

The requirements for canola storage facilities differ little from those for cereals. The nature of canola seeds and the fact that canola historically has been more valuable than an equal volume of cereals impose greater demands on storage structures. Canola is very sensitive to heating in storage and, therefore, requires better construction to exclude moisture. The small size and free flowing characteristics of canola mean that high-quality construction is necessary to prevent leakage. Roof and door openings, joints between structural components (roof to wall, wall to floor), and even bolt holes must be sealed carefully to avoid losses. The problems of heating and moisture migration tend to be more severe in large storage structures. Thus, canola should be stored in the smallest bins available, without sacrificing convenience and efficient handling.

Construction of Storage Structures

Some authorities have advocated the use of wooden, rather than steel, granaries for storing canola because they "breathe," thereby allowing heat and moisture to dissipate. However, the porous nature of these structures makes control of leakage difficult and also provides access for the influx of moisture, insects, and rodents. Steel granaries require almost no maintenance and can be more easily sealed against pests and weather. If some conditioning of hot or damp grain is necessary, metal bins are best suited to the controlled movement of air through the grain mass.

Regardless of the construction material used, storage structures must be as weatherproof as possible, yet still allow easy access to the bin for sampling and monitoring. The weatherproofing process must include the floors of bins set on grade. Concrete floors may resist the movement of water through the slab, but moisture can still enter the bin in the form of vapor. For this reason, a vapor barrier such as polyethylene should be placed between the concrete and the gravel base.

Conditions Necessary for Safe Storage

Conditions for successful storage of canola seed depends upon the moisture and temperature conditions. Grain absorbs moisture from the air or gives up moisture to it, depending upon the relative humidity of the surrounding air and on the moisture content of the seed. The oil fraction of canola seed absorbs less moisture than the starch and fiber fractions, so the equilibrium moisture content for canola is much lower than wheat. Canola seed must be stored at lower moisture content than cereal grains to prevent spoilage. Moisture levels of 8–9% at temperatures below 20°C are necessary for long-term storage. The relationship of canola seed moisture content and temperature to safe storage is shown in Figure 1.

Any combination of canola seed temperature and moisture content to the left of the bar on the chart is acceptable for longer-term storage. Only under conditions of <9% moisture and cooler than 15°C, does canola require only occasional monitoring. The chart does not allow for deterioration due to infestation by insects and mites that can occur in hot, dry seed. High moisture content but low temperature, or high grain temperature even though the grain is very dry, serves as warnings that extra attention is needed.

The optimum temperature for rapid growth of insects is in the range of 30–35°C; their activity is greatly retarded by temperatures below 18°C. If the grain is cool and dry, insects will not thrive. However, seed may go into storage at acceptable levels of moisture content and temperature and at a later date develop pockets of high moisture and temperature, which are favorable for insect activity. Infestation of hot and dry seed by insects and mites will reduce the safe storage time.

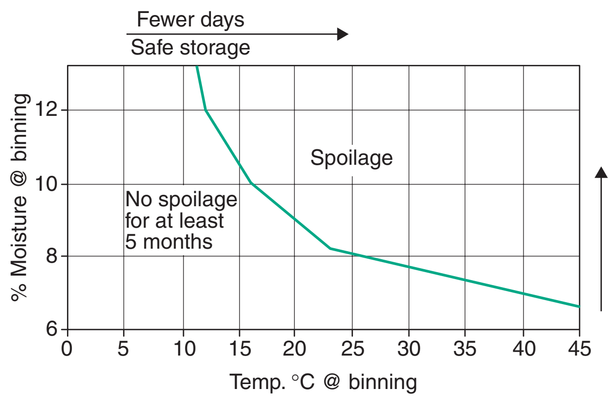

Figure 1 Canola storage time chart. (Reproduced with permission from Thomas PM (1984) Swathing – combining, storage, and conditioning of canola. In: *Canola Growers Manual*, pp. 1101–1215. Winnipeg, Manitoba: Canola Council of Canada.)

Seed moisture content is fairly uniform throughout a bin when canola is first stored. Over time, air movement through convection in the bin may relocate moisture, bringing some canola to a critically high moisture content. Convection currents are caused by temperature differentials between the grain temperature, and ambient temperature.

Factors Contributing to Storage Problems

Even though the seed moisture content and temperature have been measured and determined to be safe, problems may still occur. The severity of the problem may depend on how close the moisture–temperature relationship is to the critical line shown in Figure 1. If all the canola in a storage bin becomes damp and warm, immediate and positive action must be taken to condition the grain.

Quality canola may be stored for 2 or 3 years if its moisture and temperature are properly maintained. To successfully store canola for periods of 6–24 months, special attention must be paid to conditioning and monitoring.

Heating of Stored Canola

If the stored crop is not sufficiently dry and cool, its own respiration and the respiration of microorganisms and insects will increase the temperature of the grain mass. If left unchecked, this can lead to heating of canola, where damage occurs from microorganism activity and oxidation. Heating affects the viability of the seed. A slight degree of visible heating brings about a drastic reduction in germination. Heating of the seed lowers the quality of the protein in the meal and causes large increases in free fatty acid content. Free fatty acids are a complete loss to the processor and must be refined out of the oil. The oil from heated seed has poor quality. Heating produces a strong tobacco-like odor in the oil and meal that is difficult to remove by processing.

Conditioning

Many producers must provide storage for significant portions of each crop for one or more years. Frequently, harvesting the canola in this state is difficult, if not impossible. Furthermore, processes that occur in storage facilities can cause deterioration in the quality of the canola, even when it has been harvested under ideal conditions. These factors illustrate some reasons for conditioning canola. Conditioning could refer to all treatment of the canola between the time it is harvested and delivered to a selling point, but the term usually describes those processes that involve the movement of air through the grain.

The advantages of conditioning canola include:

- avoiding spoilage in storage;
- extending the harvest season; and
- reducing field losses.

Canola conditioning systems can be divided on the basis of both the purpose of the operation and the state of the air used in the operation. The simplest conditioning operation involves cooling of tough or dry canola, while some elaborate systems remove a considerable amount of moisture from the grain before cooling it for storage. Natural air systems, as their name implies, use the surrounding or ambient air to condition the grain. In most cases, there is no deliberate modification of the conditioning air. Heated air conditioning systems, on the other hand, use energy to heat the ambient air before its use in conditioning. The heated air has a lower relative humidity and, therefore, increased drying potential. The increased drying ability of heated air, combined with the high airflow rates typically used, give these systems a large capacity for drying canola.

Combinations of these systems, involving two or more of the operations, are also used.

Summary

Although canola is a small-seeded oilseed crop, many of the same principles that are used in the harvest, transport, and storage of other small grain cereals and oilseeds are used in the handling of canola. Specific factors, unique to canola, need to be taken into account, in order to successfully handle this crop relative to other small seeded crops.

Processing

J K Daun, Canadian Grain Commission, Winnipeg, MB, Canada

Introduction

Canola, also known as oilseed rape, has become one the most important oilseeds in world production, with the annual production of rapeseed reaching ~33 million tons (Mt) during the 1990s. Rapeseed oil has accounted for ~10% of the total world production of fats and oils over the same period and the proportion has been closer to 14% in recent years. Over the past years, rapeseed destined for human consumption has been changing in composition due to plant breeding efforts. These new varieties, low in erucic acid or both erucic acid and glucosinolates, have come to be known as low erucic acid rapeseed. In many parts of the world, rapeseed varieties with low erucic acid and glucosinolates are known as canola.

Canola and low erucic acid rapeseed are the leading varieties of rapeseed grown in the major producing areas of the world except China and India. However, low erucic acid rapeseed production in China is increasing, reaching ~50% of total production of oilseeds in that country in 1998. While most oilseeds are restricted to a single species, canola and rapeseed may include seed from the species *Brassica napus* L., *Brassica rapa* L., or *Brassica juncea* L. While *B. napus* predominates in most of the world, significant

amounts of spring-type *B. rapa* are grown in Canada and northern Europe while in India, rapeseed grown includes *B. juncea* and a Toria type of *B. rapa*. The multiplicity of species, each with different seed structure and characteristics, has created some challenges for processing. In addition, canola and rapeseed processing has the additional difficulties of dealing with glucosinolates and their hydrolysis and also, especially in *B. napus* grown in short season conditions, with significant levels of chlorophyll pigments in the oil.

Canola and rapeseed are classified as soft oilseeds. They are small, generally round seeds (~250–500 seeds per g). They are dicotyledons and the cotyledons are the major oil storage sites. The seeds possess hulls (testa) that are thin and difficult to remove. Seeds usually contain ~35–45% oil and ~18–23% crude protein (leaving an oil-free meal with 35–40% crude protein).

The principal objective of canola and rapeseed processing is to remove the oil from the seed and to process that oil to a final product for use as salad oil, margarine stock or shortening, or other vegetable oil products. At the same time, the solid portion of the seed is processed to provide an edible meal product used as a high-protein supplement in animal feeds. This article describes the most common practices for canola processing and also indicates current trends towards processing techniques that use alternate technologies which are either friendlier to the environment or produce a higher quality product.

Primary Processing – Prepress-Solvent Extraction and Alternative Techniques

The most common extraction processes for oilseeds with a high oil content, such as rapeseed and canola, sunflower seed, and flaxseed involves a combination of pressure and solvent extraction processes to remove the oil from the seed (Figure 1).

Seed Preparation

Seed arriving at an extraction plant is first cleaned to remove stones and any impurities that will impair the quality of the product or the efficiency of the extraction process. Seed-cleaning equipment usually operates with a combination of the processes of aspiration, sieving, and indent cleaning. At present, hull removal is not a common option although it is a feature of some "green" processing plants.

In some extraction plants, especially in those where seeds have very low initial temperatures and moisture content (e.g., from the Canadian prairies in winter), there may be adjustments in temperature (up to

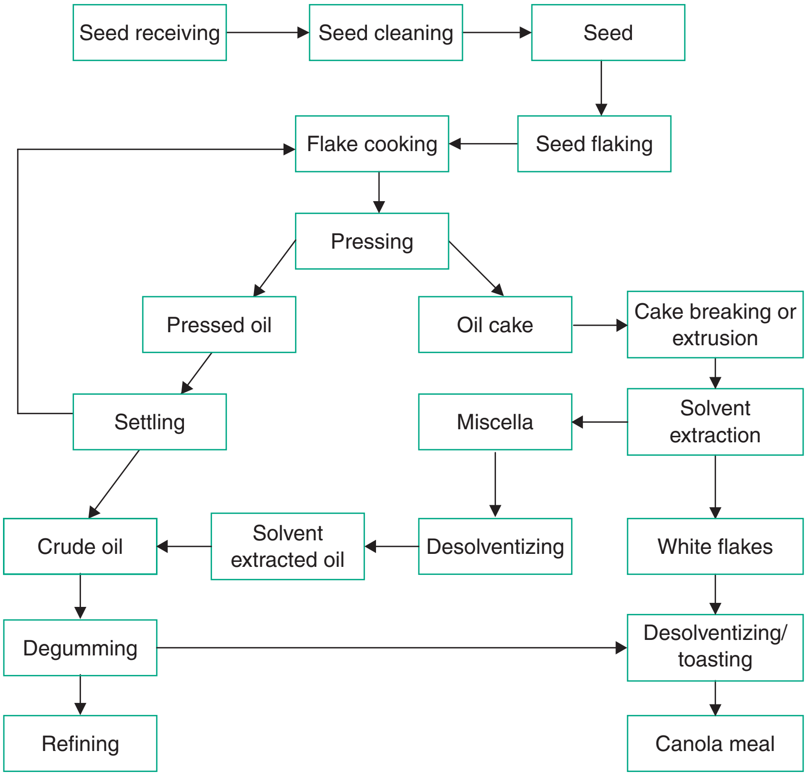

Figure 1 General flowchart for canola prepress solvent extraction technique.

30–40°C) and moisture content (~8%) to avoid seed-shattering in the flaking process.

After cooking, the seed is passed through flaking rolls that flatten it to a thickness of ~0.25 mm. This process helps rupture cells to free the oil and makes it easier for the solvent to percolate through the seed.

The flaked seed is usually cooked in order to inactivate enzymes that might cause problems during later processing. In canola and rapeseed, the key enzymes are myrosinase, which catalyzes the hydrolysis of glucosinolates releasing oil-soluble sulfur compounds and lipoxygenase. This in turn catalyzes the formation of hydroperoxides that later break down to form compounds with an undesirable flavor. Canola is often cooked in stack cookers with temperatures reaching as high as 90°C during the process. Achieving a balance of cooking temperature and time is important. If temperatures exceed 110°C, problems may be encountered due to the thermal degradation of glucosinolates.

Oil Removal

From the cooker, seed flakes are passed through a screw press, also known as an expeller. These consist of rotating screw shafts in a cylindrical barrel. The barrel "staves" consist of steel bars that have small spaces between them to allow the oil to flow out. Pressure is created in the barrel by an adjustable choke at the discharge end. This squeezes out ~70% of the oil, which is routed to a settling tank. Solid material from the settling tank is rerouted through the conditioning stage.

The material leaving the press has ~16–20% oil remaining. This material may be broken, or in some plants extruded to form expanded collets that have improved extraction properties. The cake is sent to the solvent extractor, in which a solvent dissolves the oil from the meal. It is important that the material entering the solvent extractor be cooled below the boiling point of the solvent during its conveyance to the extractor. A variety of extractor designs are used. In most, the process takes place in a succession of stages with the cake first being extracted with a solvent that already contains oil. Fresh solvent is used for extraction at the last stage. This process is known as a counter-current extraction process and provides the most efficient means for extraction of the cake. The cake leaving the extractor is known as "white flakes" and has typically less than 1% oil remaining.

The solvent is separated from the oil and the meal by distillation. It is important to reclaim and recycle as much solvent as possible, for both economic and environmental reasons, in particular to avoid the emission of significant amounts of solvent into the atmosphere. A processing plant may loose as much as 2 l of hexane for every metric ton of seed processed.

Alternative Solvent Uses

The solvent most commonly used for extraction is hexane or hydrocarbon mixtures rich in hexane. Aside from being flammable and potentially explosive, there are health concerns about exposure to hexane, particularly related to development of nerve problems after chronic exposure. This has resulted in increasingly stringent environmental controls on plant emissions and concerns about the residues of hexane in oilseed meals. As a result, there has been research into the use of alternative solvents for oil extraction. The solvents investigated have included a large number of volatile hydrocarbons, halogenated hydrocarbons such as trichlormethylene, oxygenated hydrocarbons such as ethers and alcohols, water and supercritical fluids.

Use of Enzymes – Alternative Processes

In order to reduce the need for high temperature and pressure and the use of solvents, there has been considerable research into the use of enzymes to break down cell walls allowing the seed to be processed, perhaps even using water to assist in separating the oil and meal. A "green" process plant is under operation in Denmark.

Direct Pressing – Cold Pressing

Cold pressing is a traditional method in which the seeds are not heated before, during, or after the pressing process. Seeds are selected, cleaned, and flaked as described above; they are then mechanically pressed at a slow pace to limit friction and to avoid elevating temperatures above 60°C. Retrieval of oil through this process is usually much lower than through prepress-solvent or solvent extraction processes. Therefore, the residual meal has higher levels of oil left over. Its color, taste, and odor are much more pronounced than those of refined oils. The price of cold pressed canola oil tends to be higher because of the lower recovery of oil. Cold pressed canola oil is generally sold in bottled form directly to consumers.

Secondary Processing of Oil

Once the oil has been extracted from the seed, further processing is usually necessary to remove undesirable components and to make the oil suitable for functional uses. Traditional further processing, often referred to as "refining," employs the steps detailed below (Figure 2).

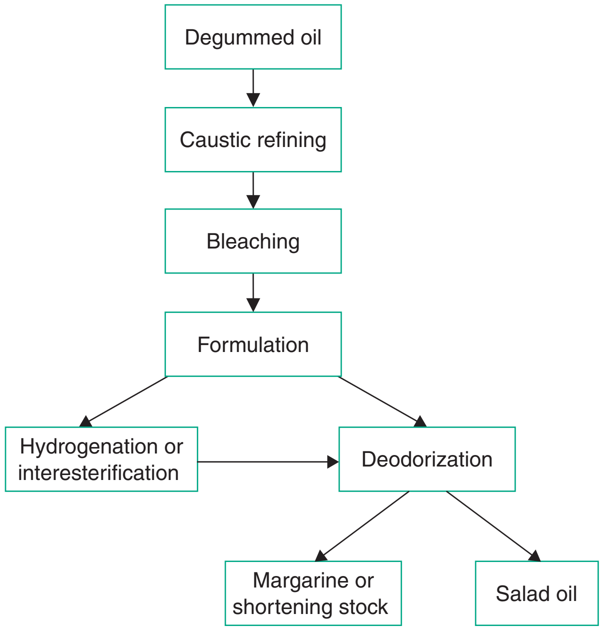

Figure 2 Secondary processing of canola oil.

Degumming (or Desliming)

This process removes the phospholipids (lecithin or gums) from the oil. It involves washing the oil with water (which may contain other ingredients such as phosphoric acid or metal-sequestering agents) to cause the phospholipids to precipitate from the oil. The heavier phospholipid/water component is separated from the oil by centrifugation. Traditional water degumming produces oils with phosphorus levels of ~30 ppm. Most oils today are degummed by processes that involve the use of acidic solutions and careful temperature and mixing regimens. The process is known as super-degumming or acid degumming and produces oil with less than 2 ppm of phosphorus.

Gums, especially from soybean, are often treated to recover lecithin that is used as an emulsifier in the food industry. Because soybean-based lecithin is plentiful and relatively cheap, in Canada, gums removed during processing of canola are usually added back to the meal as a source of energy. Canola and rapeseed lecithin tends to have an undesirable color due to the presence of chlorophyll pigments. Commercial rapeseed lecithin is available in Europe where its production has been promoted by the desire to avoid genetically modified soybean products.

Refining

The refining process is designed primarily to remove the free fatty acids from the oil. Free fatty acids are formed by the hydrolysis of the triglycerides in the oil. The fatty acids are undesirable as they impart an unpleasant metallic taste to oils. Two processes, caustic refining and physical refining, are currently used to remove free fatty acids.

In caustic refining, the oils are first treated with ~0.05–0.1% of concentrated phosphoric acid to precipitate phosphatides. The oil mixed with carefully measured amounts of 12% aqueous sodium hydroxide (caustic soda), usually ~2–3%. The sodium hydroxide reacts with the free fatty acids to form water-soluble soaps. The soaps and phosphatides are removed by centrifugation. Some oils are also refined in the presence of the solvent or miscella. This process involves a combined degumming and refining step and may produce oil with better color.

Physical refining cannot be carried out successfully on oils with high levels of phosphorus and acid degumming is a prerequisite. In the physical refining process, the acid-degummed oil is first subjected to a further phosphoric acid pretreatment followed by a bleaching process with acid-activated clay at ~100°C. The fatty acids are removed by distillation under low pressure in the presence of steam. This process is very similar to the deodorizing process described below. While many initial studies of physical refining demonstrated that it was particularly suitable for canola or rapeseed oil, rapeseed oil today is still largely processed by caustic refining.

The fatty acids removed by refining are referred to as soap stock. This product may be acidulated and sold as an industrial chemical. Soap stock, either with or without acidulation may also be added to the meal.

Bleaching

Color bodies, particular chlorophyll, as well as some oxidation compounds and iron are removed from the oil by mixing the oil with 1–3% of an absorbing solid, usually diatomaceous earth or bleaching clay. The clay oil mixture is mixed and dried under vacuum at ~100°C for 5–30 min. Occasionally, small amounts of activated charcoal may be added. The color bodies are absorbed onto the solid. After filtration, the oil is tested to ensure it meets color standards specified in contracts for each oil type. The color testing equipment is often based on the Lovibond system that measures oil color by comparing it with standard red, yellow, and blue filters. The high levels of chlorophyll pigments, often found in canola oil produced in areas where the seed does not have time to fully mature, are difficult to remove from the oil. Besides imparting an undesirable color to the oil, these pigments, when present in excessive amounts, have been

associated with the development of off-flavors due to oxidation, even though the chlorophyll levels are reduced to below industry specifications during the processing stage.

Hydrogenation

Liquid vegetable oils, particularly canola, soybean, and sunflower oil are highly unsaturated making them susceptible to oxidation especially when heated to frying temperature. In addition, the uses of oils in margarines or shortening require that the fat is solid or semisolid to obtain the functionality required. Unsaturated liquid oils can be made more solid using hydrogenation.

Hydrogenation involves treatment of the oil with hydrogen in the presence of a catalyst under controlled pressure (100–300 kPa) and temperature (160–200°C). Two processes take place. In the first process, hydrogen is added to the double bonds, increasing the stability of the oil to oxidation during frying and raising the melting point of the oil. In the second process, some of the double bonds are converted from the naturally occurring *cis* form to the *trans* form. *Trans* fats also have higher melting points than *cis* fats. When treating liquid oils for reduction of the number of double bonds, the hydrogenation process is made selective to ensure that the hydrogen reacts with the highly unsaturated linolenic acid first. When preparing solid fats, it is more economical to maximize the *trans* production.

The canola and rapeseed industry has encountered a problem while using these oils for preparing margarines and shortenings. The high proportion of C_{18} fatty acids in canola oil and low erucic acid rapeseed oil mean that the desirable small β' crystals in the hardened fat tend to be unstable and convert eventually to large β' crystals. This problem has been overcome to a certain extent by mixing small amounts of palm oil into the margarine or by adding a crystal stabilizer.

Health concerns about *trans* fat have resulted in changes in processing. Of late, some solid fats are manufactured using the transesterification process with solid palm oil fractions or with fully saturated oils from the hydrogenation process.

Inter-esterification

In order to prepare a solid fat without resorting to hydrogenation, the liquid canola or rapeseed oil may be inter-esterified with a harder fat such as palm oil or a fully hydrogenated vegetable oil. Adding a catalyst to the oil results in the fatty acids rearranging themselves on the glycerol backbone, providing new triglycerides with different properties.

The process involves the addition of ~0.05% of the catalyst sodium methoxide to the heated (150°C) oil as a powder under agitation. After 30 min, the oil is cooled and the base is neutralized with phosphoric acid before washing and bleaching. This process is in use to prepare nonhydrogenated canola margarines.

Winterizing or Dewaxing

Oils may contain small amounts of waxes and fully saturated triglycerides that may precipitate or haze when the oil is stored at refrigerator temperature. While these compounds have no undesirable health or flavor effects, consumers see the haze as unfavorable. Deodorized oils may be treated to a cooling period followed by filtration of any precipitate. This process reduces the amount of haze formed during refrigeration. While canola and rapeseed oils were originally perceived to be free of waxes and hence not require winterization, waxy sediments have been found in canola and rapeseed oils in recent years. As a result, plants now routinely winterize the oil.

Deodorizing

Refined, bleached, and hydrogenated or inter-esterified oils usually contain small amounts of volatile flavor components as well as low levels of free fatty acids generated during bleaching. These are removed by a distillation process known as deodorization during which the oil is treated with steam (2–4%) at high temperature (260–265°C) and low pressure (2–4 mmHg). Deodorization also removes some sterols and, more importantly, the antioxidant tocopherols from the oil. Tocopherols, sterols, and fatty acids are valuable by-products used in the pharmaceutical and chemical industries. However, a minimum level of tocopherols is required in the oil to prevent oxidation. The deodorizing process is designed to allow the most economic combination of tocopherol recovery without jeopardizing oil stability.

Refining Loss

The above steps result in a slight loss in the amount of oil originally extracted from the seed. This refining loss is significant and is impacted by the quality of the original seed. Lower quality seeds give oils that are more expensive to refine. They require greater use of chemicals and treatment time and also have a higher refining loss.

Formulation

Deodorized oil may be bottled directly or, more often, small amounts of citric acid or antioxidants are added to improve the oil's shelf life.

Standards

Standards for crude and refined, bleached and deodorized canola oil have been published by the Canadian General Standards Board (Tables 1a and 1b) and also in trading rules published by the National Institute of Oilseed Processors and national trading organizations such as the Canadian Oilseeds Processors Association.

Meal

Removal of solvent from the meal is carried out in a desolventizer. This is a vertical tank equipped with heated trays and agitators. The meal enters the top of the tank and is treated with reduced pressure and sometimes live steam to evaporate the hexane. During the process, the temperature may reach as high as 110°C and some glucosinolate breakdown and denaturation of the protein occurs. Newer processes have placed a great emphasis on carefully controlling this process in order to avoid excessive denaturation of protein in order to obtain the best quality meal possible. In areas where there is no external market for gums (q.v.), the gums may be added back to the meal at this point. Canola meal typically has more than 36% crude protein and usually ~3% neutral lipids. Canola and rapeseed meal are valuable sources for protein supplement in animal feeds, particularly when the deficiencies and strengths of canola meal amino acid composition are combined with other protein sources such as pulses (soybean meal or pea meal).

Oilseed protein, and in particular soybean protein, is finding wide use in food products particularly as a result of the FDA's allowance of a health claim for soy protein in reducing cholesterol. Oilseed proteins (isolates or concentrates) are extracted from oilseed meals using aqueous solvents. The extracted proteins are precipitated using a number of different reagents and the precipitate is collected by filtration. While most protein isolates from oilseeds have been developed with soybean, there has been recent interest in the use of canola protein isolate with a pilot plant being established for this process.

CARBOHYDRATE METABOLISM

R N Chibbar, S Ganeshan, M Båga, and R L Khandelwal, University of Saskatchewan, Saskatoon, SK, Canada

Published by Elsevier Ltd.

Introduction

Carbohydrates constitute two-thirds to three-quarters of plant dry-matter, and are the major components of plant storage organs. Cellulose, the most-abundant plant carbohydrate provides structural integrity to the plants and is used for fiber and fuel by humans. In seeds, carbohydrates provide energy and substrates for germination and initial growth of a new plant. The major reserve carbohydrate present in grains is starch, which constitutes a major source of calories in the human diet and animal feed. Carbohydrates form the basis of several important industries in the food and feed sectors, and provide renewable and environmentally friendly raw materials for industrial applications such as biodegradable plastics, adhesives, and ethanol-based fuels. With the development of genetic modification technologies, the biosynthesis of carbohydrates can be altered *in planta* to generate novel products for various food, feed, and nonfood applications. This article will describe the structure, occurrence, and distribution of some of the common storage and structural carbohydrates present in the grains of major crops. The biochemical reactions occurring during the biosynthesis of carbohydrates and their utilization during seed germination will be presented.

Carbohydrates

Definition and Classification

The term carbohydrate is derived from its basic elemental formula $[C_x(H_2O)_y]$, in which carbon is joined to hydrogen and oxygen present in the same ratio as in water. Chemically, carbohydrates are polyhydroxy aldehydes or ketones, their simple derivatives or their polymers. Carbohydrates in grains are classified based on their chemical structures or their digestibility when consumed by humans as food or by livestock as feed. Based on the polymeric nature of carbohydrates, they are classified as monosaccharides, disaccharides, oligosaccharides, and polysaccharides (Figure 1). Monosaccharides are the simplest of all sugars, contain at least three carbon atoms, and are the building blocks of all carbohydrates. The most common monosaccharides in grains are the hexoses (fructose, glucose, and galactose) and the pentoses (arabinose and xylose). Two sugar moieties joined by a glycosidic bond (an oxygen bridge) form a disaccharide. Upon hydrolysis of disaccharides, the glycosidic bond is split to yield the component monosaccharides. Sucrose and maltose are the most commonly occurring disaccharides in most grains. Oligosaccharides include the sugars that contain 3–20 sugar molecules joined by glycosidic bonds. The most common oligosaccharides are soluble α-galactosides, characterized by galactose moieties joined by $\alpha(1,6)$ linkages. In legumes, raffinose, stachyose, verbascose, and α-galactosides are the most common oligosaccharides that constitute 6–18% of the legume seeds dry weight. Polysaccharides are polymers with more than 20 monosaccharides joined together by glycosidic linkages. These are complex molecules because of the diversity in monosaccharide units and type of linkages present in the polysaccharides. Some of the most common polysaccharides present in grains are starch, cellulose, and xylans, of which xylans include pentosans, β-glucans, and arabinoxylans. In relation to human and animal nutrition, carbohydrates are also classified as available and unavailable. The available carbohydrates represented by sugars and starches are broken down and absorbed by the human and animal digestive tract to give energy to the body. Structural cell-wall carbohydrates such as cellulose, hemicellulose, and nonstarch complex carbohydrates, e.g., xylans are categorized as unavailable carbohydrates because they are not assimilated by the digestive tract. The unavailable carbohydrates are also often referred to as dietary fibers.

Distribution in Important Grains

All the above-described carbohydrates are present in most grains, where they form the major constituent of the dry weight (Table 1). However, in oil seed grains, such as *Brassica* spp., lipids and proteins are the major storage grain components and carbohydrates make up only one-quarter of the grain dry-weight. In cereal grains, the total concentration of mono-, di-, and oligosaccharides varies from less than 1–3% (Table 2). Corn kernels contain the highest percentage of glucose and fructose, whereas in barley, sucrose is the major free sugar. Wheat grains have the highest concentration of raffinose among the cereal grains (Table 2).

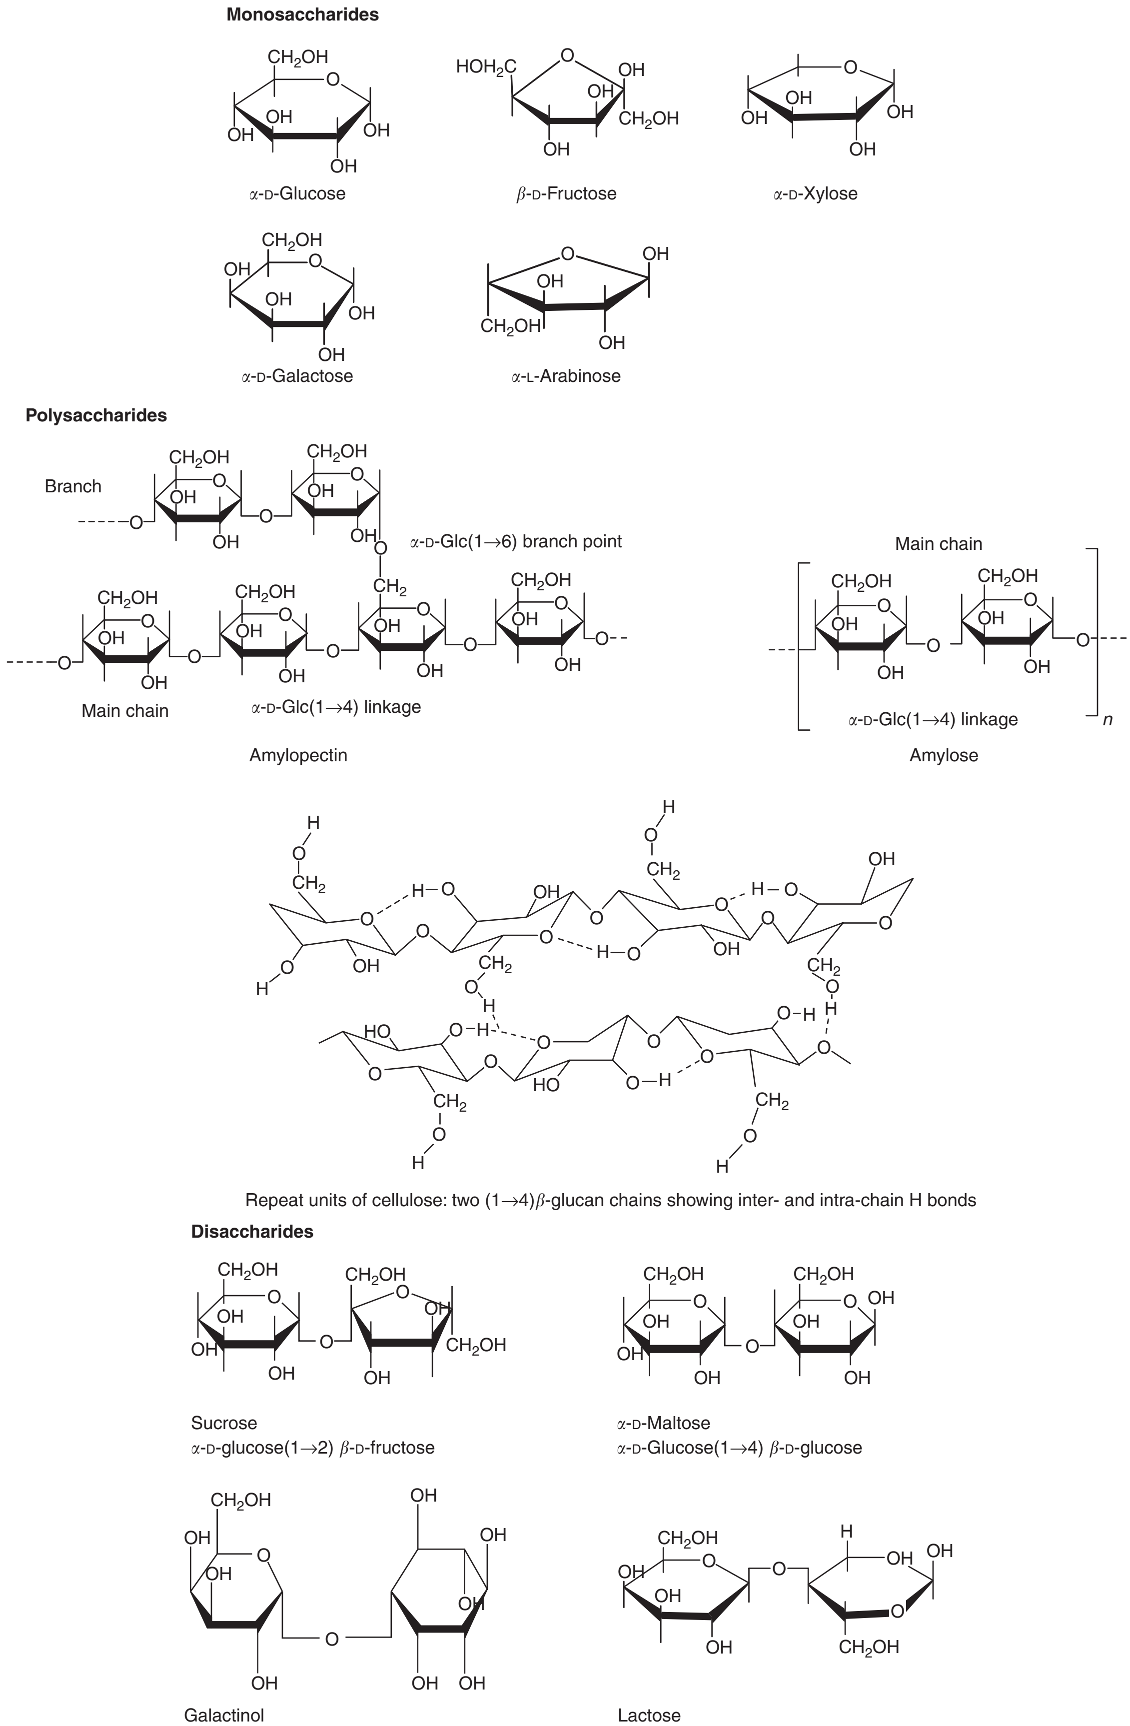

Figure 1 Classification and chemical structures of representative carbohydrates found in common grain crops.

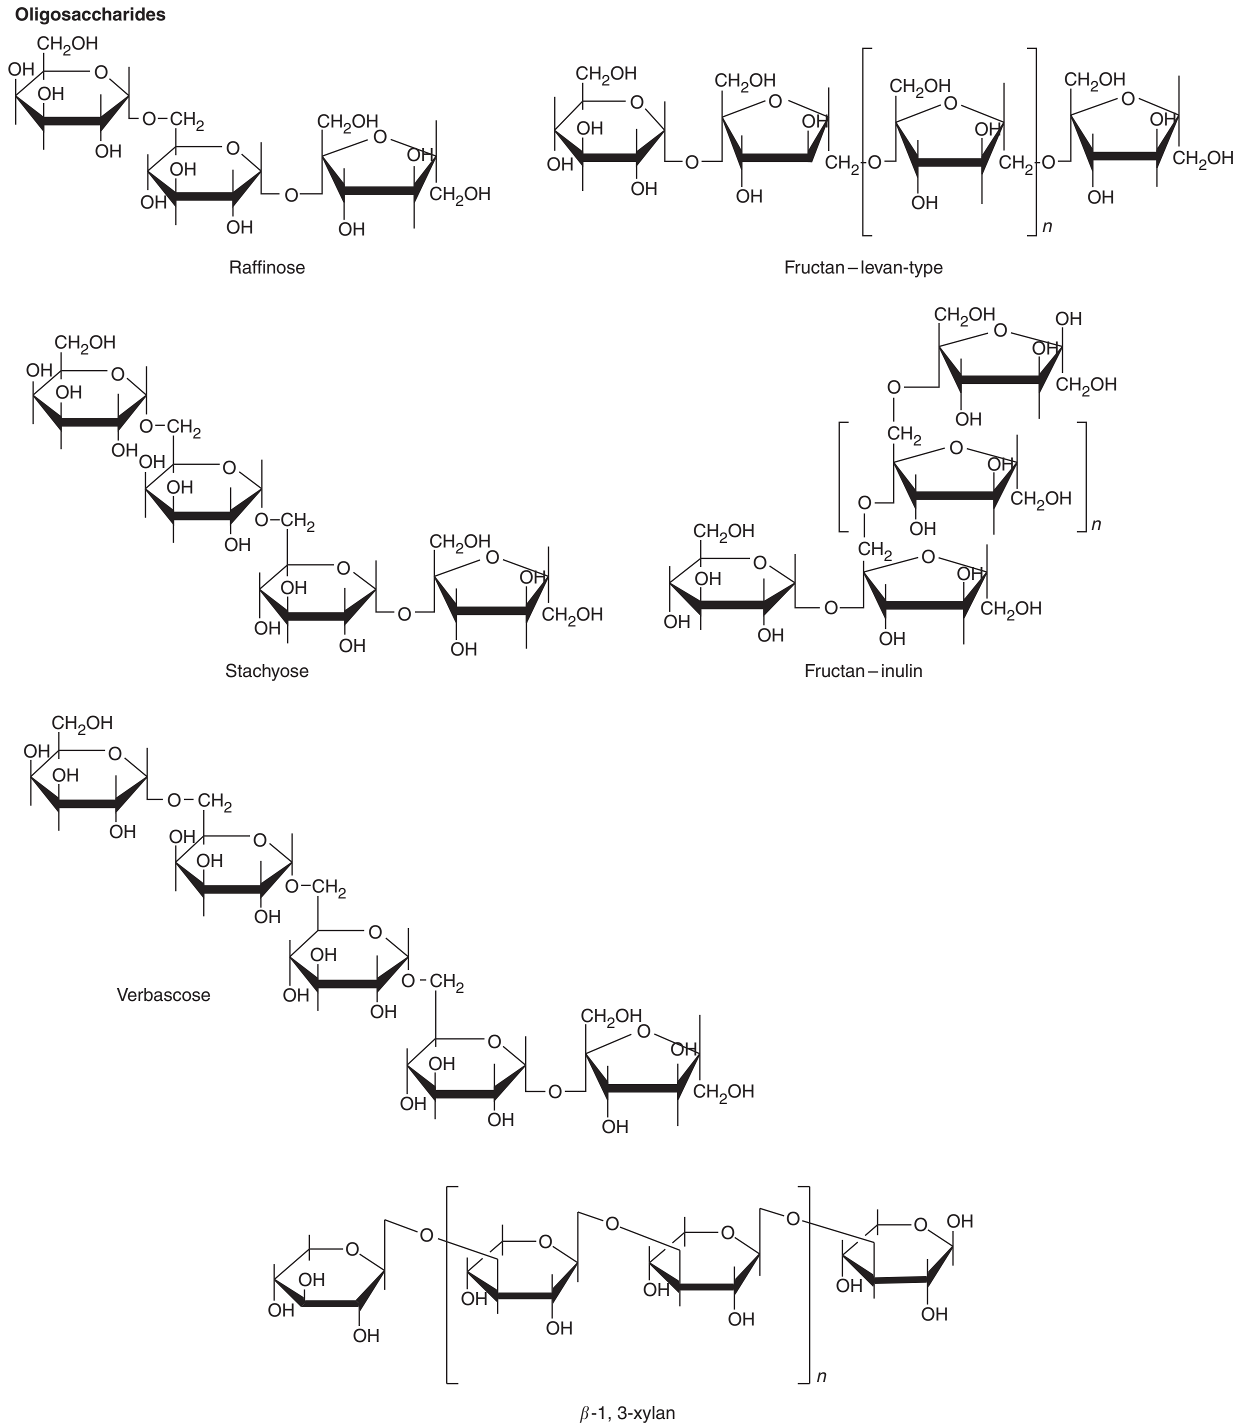

Figure 1 Continued.

Legume crops in general have a higher concentration of di- and oligosaccharides as compared to cereal grains (Table 3). Especially chickpeas have a high concentration of soluble sugars, of which sucrose is the major component. Lentils and peas have higher concentrations of stachyose and verbascose as compared to other legumes. Starch is the major storage carbohydrate in cereal grains, where it forms two-thirds to three-quarters of the dry weight. However, in oat, the starch concentration is slightly less, ranging from 50% to close to 60%. Legume seeds also contain 50% starch, except lupins and soybeans in which only 0.5–1.4% of the dry weight is starch. The structural carbohydrates, which constitute the major

contributors of unavailable carbohydrates (dietary fibers), range in distribution from slightly above 5% in rice to almost one-third of the grain dry-weight in barley. In grain legumes, chickpeas have a higher concentration of total nonstarch polysaccharides, whereas the concentration of total dietary fiber corresponds to that of other legumes (Table 3). The major nonstarch complex carbohydrate in grain legumes is cellulose which represents about one-eighth of the grain dry-weight in the majority of the grain legumes (Table 3).

Metabolism

Plants have the ability to convert simple nutrients such as carbon dioxide, water, and inorganic ions into intermediates leading to the biosynthesis of complex molecules, such as nucleic acids, proteins, lipids, polysaccharides, and secondary metabolites needed for growth and development (Figure 2). Through the process of photosynthesis, light energy is captured to fix reduced carbon dioxide and water into a simple carbohydrate backbone, CH_2O. The reaction takes place in chloroplasts, in which CO_2 entering the Calvin cycle is incorporated into 3-phosphoglycerate (3-PGA) molecules, which are subsequently converted to triose-phosphates. In addition, the absorbed light energy produces reducing equivalents and ATP for several biosynthetic reactions needed for plant growth and development. The reactions associated with light absorption are diurnal, which results in large variations in nutrients available to plants during light and dark periods. However, plants have developed considerable flexibility in their metabolism to cope with fluctuations in nutrient concentration. Plant cells can be envisioned to have a series of metabolic intermediate pools, which are interconnected to each other through enzyme reactions or transport mechanisms that are often reversible (Figure 2). According to the physiological need(s) of a plant, metabolites can be added to or withdrawn from these pools. Two metabolite pools of the reductive pentose-phosphate pathway and its intermediates are the triose-phosphate (3-PGA and dihydroxyacetone phosphate, DHAP) pool and the hexose-phosphate (glucose-1-P; glucose-6-P, fructose-1-P, ADP-glucose) pools, which play major roles in carbohydrate metabolism (Figure 2).

The triose-phosphates are either transported by triose-phosphate transporters to the cytosol, or converted to other phosphorylated compounds, such as fructose-6-phosphate, in the plastid. The plastidial fructose-6-phosphate is used both for regenerating ribulose-1,5-bisphosphate and producing

glucose-1-phosphate. Glucose-1-phosphate, when converted to ADP-glucose by ADP-glucose pyrophosphorylase (AGPase), is the immediate precursor for starch biosynthesis as described below. Starch synthesized in the chloroplast during the day is known as transitory starch, as it is degraded to maltose, glucose, hexose-phosphates, and triose-phosphates at night. Some of the starch degradation products are transported to the cytosol and are converted to sucrose, the major transport sugar. Sucrose through symplastic or apoplastic transport enters the phloem, through which it is mobilized to the storage tissues, where symplastic or apoplastic up-take into sink cells takes place. The transported sucrose is further converted to substrates that give rise to diverse carbohydrates present in grains of different crops as described above. The hexose-phosphate pool also plays an important role in starch and sucrose utilization by the plants. During the glycolytic pathway, which acts in reverse of the triose-phosphate synthetic pathway during photosynthesis, starch and sucrose are oxidized to provide energy and hexose-phosphates that on phosphorylation contribute to the hexose-phosphate pool. In addition, the glycolytic reactions provide several intermediates that contribute to the synthesis of proteins, lipids, and organic acids (Figure 2). These compounds are important grain components, and are described in other articles.

The hexose-phosphate pool is an important converging point for both carbohydrate synthesis and degradation, and thus is considered to play an important role in carbohydrate metabolism in plants. The main components, glucose-1-phosphate, glucose-6-phosphate, and fructose-6-phosphate, are readily interconvertible when present in the same system. However, in plants the hexose-phosphates are compartmentalized to the plastids and cytosol. In photosynthetic tissues, the plastidial and cytosolic hexose-phosphate pools are independent of each other and their exchange is often restricted. Therefore, the regulation of the carbohydrate metabolism in plants is more complex than in other organisms, where such subcellular compartmentalization of hexose-phosphates is not present.

Sucrose

Sucrose is a nonreducing disaccharide, formed by joining the glucose with a fructose molecule. Sucrose accounts for most of the CO_2 fixed during photosynthesis. It is the major form of transported carbon in plants and in some plants it is the major storage carbohydrate. The translocation of sucrose from source to sink tissues is very active during grain development when storage carbohydrates are synthesized in the

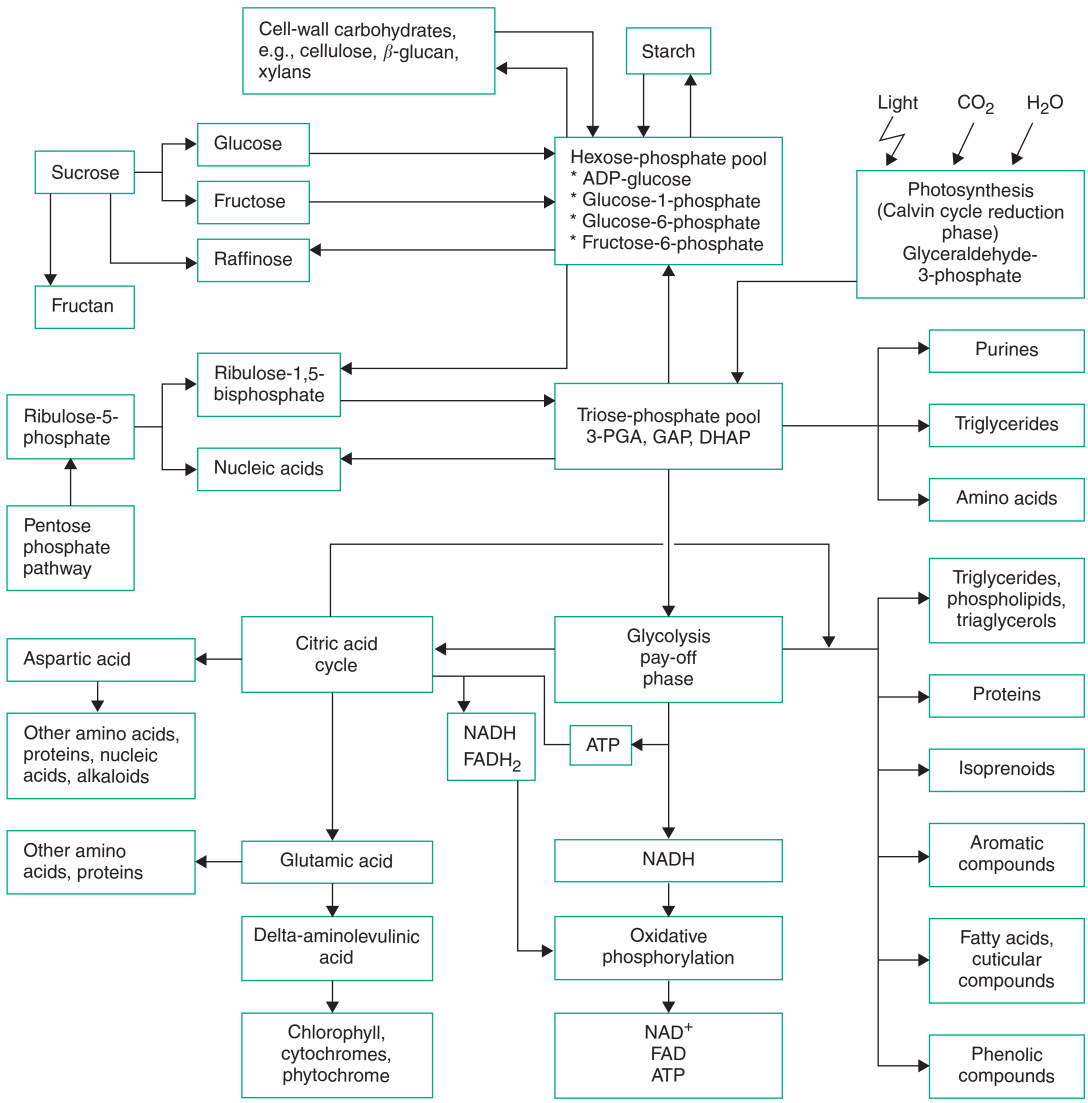

Figure 2 A schematic overview of the carbohydrate metabolism and its inter-relationship with other biochemical pathways to show the production of major plant cell constituents.

grains. A boost in sucrose concentration in seeds is observed during seed germination when stored carbohydrates are broken down to provide energy to the germinating embryo. Sucrose synthesis is most apparent in leaves, but the ability to synthesize sucrose is fairly widespread among plant cells. In photosynthetic cells, the precursor for sucrose synthesis, fructose-6-phosphate, is synthesized in the cytosol from triose-phosphates by the action of an aldolase and fructose-1,6-bisphosphatase (FBPase). In all cell types, cytosol is the site for the synthesis of sucrose, which is derived from the hexose-phosphate pool, through the concerted action of UDP-glucose pyrophosphorylase, sucrose-phosphate synthase (SPS), and sucrose phosphatase as described below. The action of UDP-glucose pyrophosphorylase controlled by the pyrophosphate concentration plays a central role as it catalyzes the entry and exit of glucose-1-phosphate from the hexose-phosphate pool.

SPS is highly active and plays a key role in regulating sucrose synthesis. Based on changes in free energy, SPS activities and turnover rates of metabolic intermediates during sucrose synthesis, it has been possible to correlate SPS activity to the amount of sucrose produced in green leaves. The SPS is deactivated by protein phosphorylation and is allosterically activated by glucose-6-phosphate and inhibited by inorganic phosphate providing an additional control of the hexose-phosphate pool. Sucrose synthase (SS) is another enzyme, which can catalyze both sucrose synthesis and degradation. This is also a cytosolic enzyme, which participates in sucrose synthesis in tubers,

but its role in sucrose synthesis in other organs such as developing grains is not very clear.

Oligosaccharides Carbohydrates that on hydrolysis give only monosaccharides are termed oligosaccharides. Depending on the number of monosaccharide residues per molecule, the oligosaccharides are classified as trisaccharides, tetrasaccharides, and so forth. Oligosaccharides in grains are synthesized from sucrose or fructose or both.

Raffinose family of oligosaccharides Second to sucrose, α-galactosides are the most widely distributed soluble carbohydrates in the plant kingdom, comprising 6–18% of the dry weight of the mature legume seed. Galactosyl cyclitols and the raffinose family of oligosaccharides (raffinose, stachyose, and verbascose) are the predominant α-galactosides and contain α-galactosidoglucose and α-galactosidogalactose bonds and are nonreducing. Raffinose oligosaccharides are nonreducing sugars and constitute an important form of transported carbon in some plants. These oligosaccharides have generally been considered to have low nutritional value, due to their indigestibility and promotion of flatulence in humans and animals. However, recently it has been found that raffinose oligosaccharides have a beneficial effect on the gut microflora and therefore is recommended in diets to prevent cancer development in the digestive tract.

Raffinose oligosaccharides are synthesized from sucrose by a stepwise addition of galactose units provided by galactinol. The reaction is catalyzed by at least four enzymes resulting in the trisaccharide, raffinose that serves as an acceptor for another galactosyl residue from galactinol, to produce the tetrasaccharide, stachyose. These two reactions are catalyzed by raffinose synthase and stachyose synthase, respectively. A specific galactosyltransferase utilizes UDP-galactinose and myoinositol to produce galactinol for raffinose oligosaccharides. The galactinol molecules are formed from UDP-galactanose and myoinositol by the action of a galactosyltransferase.

Fructans Fructose polymers (fructans) serve as soluble storage carbohydrates in ~12–15% of all flowering plants including cereals (e.g., wheat, barley, oat), forage grasses (e.g., Lolium, Festuca), vegetables (e.g., chicory, lettuce, onion), and ornamentals (e.g., dahlia, tulips). In cereals, fructans can be found in young internodes, from which fructan-derived carbohydrates are mobilized to kernels during grain filling. Besides being an energy reserve in plants, fructans have a role in regulation of osmotic pressure, sink strength, and resistance to cold and drought. The sweet taste makes fructans useful as low-calorie sweeteners and they have also found some use as fat-replacers in foods. Fructans with low degree of polymerization are promoted as a soluble dietary fiber in the human diet as they are poorly digested in the small intestine, but stimulate growth of beneficial microbes in the large intestine.

Sucrose is the primary substrate for fructan biosynthesis, which takes place in the vacuoles by the action of two or more fructosyltransferases. Sucrose: sucrose 1-fructosyltransferase (1-SST) catalyzes addition of a fructosyl residue derived from one sucrose molecule to another sucrose to form the trisaccharide, 1-kestose. 1-kestose can be further elongated by fructan:-fructan fructosyltransferase (1-FFT), which reversibly adds a fructosyl residue from one fructan (DP $\geq$ 3) to another fructan or sucrose molecule. The concerted action of 1-SST and 1-FFT results in a mixture of fructans with 10–20 fructose residues. Plant fructans show a variety of branching patterns. Barley produces bifurcose, which is composed of both inulin (β-2,1-linked) and levan (β-2,6-linked) -type fructans. The enzyme Suc:fructan6-fructosyltransferase (6-SFT), which only uses sucrose as fructosyl donor, catalyzes the synthesis of bifurcose. The liliaceous species, such as onion and asparagus, synthesize a fructosyltransferase, 6G-FFT, which catalyzes the formation of the trisaccharide neokestose formed by the transfer of a fructose residue from 1-ketose to the C6 of the glucose moiety of sucrose. The 1-FFT catalyzes extension of the fructan chain at either end of the glucose molecule.

Sugar Alcohols

Sugar alcohols are primary photosynthetic products that are accumulated temporarily in leaves during light and are translocated to other plant organs at night. As compared to the corresponding sugar, sugar alcohols have an additional hydroxyl group, and therefore, are designated as polyols, polyalcohols, or polyhydric alcohols. Mannitol, sorbitol, galactitol, and gluctinol are the main sugar alcohols, which have been studied in plants. These compounds are rare in monocots but contribute significantly to transported and stored carbon in some horticultural plants, such as members of the Rosaceae, Rubiaceae, and Plantaginaceae families. Sugar alcohols have been implicated in abiotic stress tolerance. In comparison to sucrose, sugar alcohols are more metabolically sequestered, and this has important implications in their physiological role in translocation and storage of carbohydrates.

Sugar alcohols are synthesized from hexoses or hexose-phosphates, through the consecutive action of reductases and phosphatases. In green celery tissues,

three cytosolic enzymes, mannose-6-phosphate isomerase, NADPH-dependent mannose-6-phosphate reductase, and mannitol-1-phosphate phosphatase, convert fructose-6-phosphate to mannose-6-phosphate, mannitol-1-phosphate, and mannitol, respectively. Glucitol is similarly synthesized from glucose-6-phosphate by the action of a glucose-6-phosphate reductase and a sorbitol (glucitol)-6-phosphate phosphatase.

Starch

Starch is the most common storage carbohydrate in plants. Besides being an important energy source in the human diet and animal feed, starch is also utilized in many nonfood applications, e.g., paper, pulp, and textile production, because of its excellent gelling, pasting, and adhesive properties. Since starch is a renewable and biodegradable resource, it has received increased interest for production of environmentally friendly biomaterials.

Starch is a complex macromolecule composed of two glucan polymers, an essentially linear chain amylose, and a highly branched amylopectin. Starch is normally made up of one-quarter amylose, with the remaining three-quarters being amylopectin. The two components are arranged in a three-dimensional, semicrystalline structure – the starch granule. Starches from different sources differ in their overall properties due to differences in granule size distribution and shape, amylose and lipid content, distribution of chain length in amylopectin, phosphorylation, and crystallinity. For example, native starches from pulse crops generally have a higher percentage of amylose as compared to cereal starches (Tables 2 and 3). Most of the gelling and pasting behavior of extracted starch is determined by the amylose/amylopectin ratio, amylopectin structure, and starch granule size distribution. Genetically altered starches derived from mutagenesis and breeding programs have already been commercialized.

Biosynthesis of starch in plants has been actively studied over the years but the biochemistry of amylopectin synthesis and the precise mechanism for starch granule initiation is still not clearly understood. Studies of starch mutants have so far produced a general consensus that ADP-glucose pyrophosphorylase (AGPase), soluble starch synthases (SSs), starch branching enzymes (SBEs), starch debranching enzymes (DBE; pullulanase; isoamylase), and possibly also, disproportionating enzyme (D-enzyme) catalyze the final steps leading to amylopectin synthesis. Granule bound starch synthase 1 (GBSSI) is the only enzyme committed to amylose synthesis. Since several of the enzymes exist in different isoforms, some of which vary in their subcellular distribution, enzyme specificity, temporal activity, and interaction with other enzymes, the starch biosynthesis pathway is complex. The AGPase catalyzes the reaction between Glu-1-P and ATP to produce ADP-glucose, which is the primary building block required for chain elongation to initiate starch synthesis. The priming mechanism for starch glucan polymerization in plants is unclear, but it likely involves short-chain maltodextrins that are extended and branched by the action of GBSSI, SBEI, and SSI to form a molecule with amylopectin-like backbone. The primary glucan polymer is further polymerized through cycles of chain extensions and branching catalyzed mainly by SSI and SBEII. Debranching enzymes have been proposed to play a role in starch biosynthesis by trimming the ends of the water-soluble preamylopectin molecules to produce amylopectin that can be crystallized and packaged into granules. De-branching enzymes are also suggested to degrade water-soluble glucans synthesized by starch synthases and starch branching enzymes to prevent accumulation of phytoglycogen, which cannot form granules. Observations made in *Chlamydomonas* suggest that the D-enzyme is also involved in starch synthesis and granule formation in addition to starch degradation. Polymerization of amylose is initiated from soluble malto-oligosaccharides that serve as primers for GBSS1.

Cellulose

Cellulose is the major component of cell walls and accounts for 28–30% of dry matter in forage grasses and 42–45% of wood. It is the most abundant renewable biomass synthesized on earth and has since the early days of human civilization been used for fuel, timber, fiber, and forage. Today, cellulose has additional uses as raw material for production of paper, pulp, and many chemicals. Cellulose is composed of several dozen glucan chains that are arranged parallel to each other and hydrogen-bonded to form a microfibril with an average thickness of 36 chains. The chains contain a few thousand glucose units giving an individual length of 2–3 μm, but the chains start and end at different points of the microfibril, thus extending the length of the microfibril to hundreds of micrometers.

In higher plants, cellulose synthesis occurs in a plasma membrane-bound complex known as "rosette TC." The structure contains six subunits, each composed of six glucan (cellulose) synthase molecules that are symmetrically arranged into a rosette. The subunits of the complex synthesize simultaneously 36 1,4-β-D-glucan chains that are bundled into a microfibril emerging from the rosette TC.

The basic biochemical understanding of cellulose synthase (Ces A) has mainly been obtained from studies of the bacterium, *Acetobacter xylinum*. Ces A consists of at least two subunits, one with catalytic and the other with a regulatory role. The catalytic subunit of Ces A is a progressive glycosyltransferase, which binds the substrate, UDP-glucose, derived from sucrose by the action of a membrane-bound sucrose synthase. At the initiation of polymerization, two UDP-glucose molecules are present in the substrate-binding site and as the chain elongates, glucose is added to the nonreducing end of the chain. The first plant Ces A genes were characterized in cotton and have been followed by Ces A and cellulose synthase-like (*Csl*) genes from *Arabidopsis thalliana*, rice, and poplar. In addition to the Ces A, it has been reported that membrane-anchored endo-1,4-β-glucanases may also play a role in cellulose biosynthesis, based on studies with the *Arabidopsis Korrigan* mutant and the cellulose-producing bacterium *Agrobacterium tumefaciens*.

Other Cell-Wall Carbohydrates

Other important polysaccharide components of the cell wall include cross-linking glycans, which are hydrogen-bonded to cellulose microfibrils. These glycans coat the cellulose microfibrils and link two or more cellulose microfibrils to form a network in the primary cell walls of all plants. The two major classes of the cross-linking glycans are xyloglucans (XyGs) and glucuronoarabinoxylans (GAXs), of which XyGs are present in cell walls of most dicots and almost half of all monocot species. The XyGs are made up of linear chains of 1,4-β-D-glucan with numerous α-D-Xyl units linked to the O-6 position of the glucan units. In some cases, the xylosyl units are further substituted by arabinose or galactosyl units. In addition to the two xyloglucans, some members of the Poaceae family, which includes the majority of cereal crops, such as wheat and barley, contain a third cross-linking glycan, β-glucan. This is a linear polymer that consists of 3-D-glucopyranosyl monomers joined by both $(1\rightarrow3)$ and $(1\rightarrow4)$ linkages, normally in a 2:1 ratio.

Arabinoxylans and β-glucans affect the quality and utilization of cereal grains due to their presence in the endosperm cell walls. The predominant component of starchy endosperm cell walls in barley, oats, and maize is β-glucan, whereas arabinoxylans are the major component found in rye and wheat. These compounds have a significant impact on the utilization of the grains for both food and animal feed. In wheat flour, pentosans absorb water and significantly affect the quality of baked products. The cell-wall carbohydrates are not completely digested in the stomach or small intestine of humans or other monogastic animals, but are digested by bacteria in the large intestine. They tend to reduce the absorption of mono- and di-saccharides in the gut by raising the viscosity of the gut contents, thus decreasing the levels of blood glucose and insulin. β-Glucans have been shown to significantly reduce blood cholesterol levels, when present in the diet at high levels. In addition, they have also been shown to have antibacterial, antiviral effects and accelerate wound healing. In animal feed, both gluconoarabinoxylans and β-glucans have anti-nutritional effects, as these may decrease the absorption of nutrients due to their high viscosity and indigestibility.

Cell-wall polysaccharides are synthesized from sucrose through the action of SS, UDP-glucose dehydrogenase, UDP-glucuronate decarboxylase, xylan synthase, and arabinosyl transferase that sequentially give rise to UDP-glucose, UDP-glucuronate, UDP-xylose, 1,4-β-xylan, and arabinoxylan, respectively. The action of three epimerases further convert UDP-glucose to UDP-galactose, UDP-glucuronate to UDP-galactouronate, and UDP-xylose to UDP-arabinose, respectively.

Carbohydrate Breakdown

Germination is initiated when the dry seed imbibes water and the process is completed with the elongation of embryonic axis (Figure 3). One of the first signs of metabolic activity in a germinating seed is the activation of enzymes that hydrolyze storage reserves. This process has been well characterized in cereal grains (Figure 3). A group of plant growth regulators known as the gibberellins (GA) are the first to be synthesized in the scutellum of the embryo. The GAs diffuse into the aleurone layer and induce the production of hydrolytic enzymes such as α-amylases active on the starch granules in the endosperm. The hydrolysis products are taken up by the embryo to initiate its growth. Carbohydrates stored in the endosperm or cotyledons are the primary source of energy in the developing embryo until it forms leaves and the photosynthetic process takes over to supply the necessary energy and chemical constituents for the developing plantlet.

Starch Breakdown

In cereal grains, starch is the major carbohydrate that is broken down during germination. Starch degradation occurs in three distinct phases: (1) reduction of starch granules to soluble maltodextrins; (2) degradation and de-branching of larger maltodextrins to glucose and glucose-1-phosphate; and finally

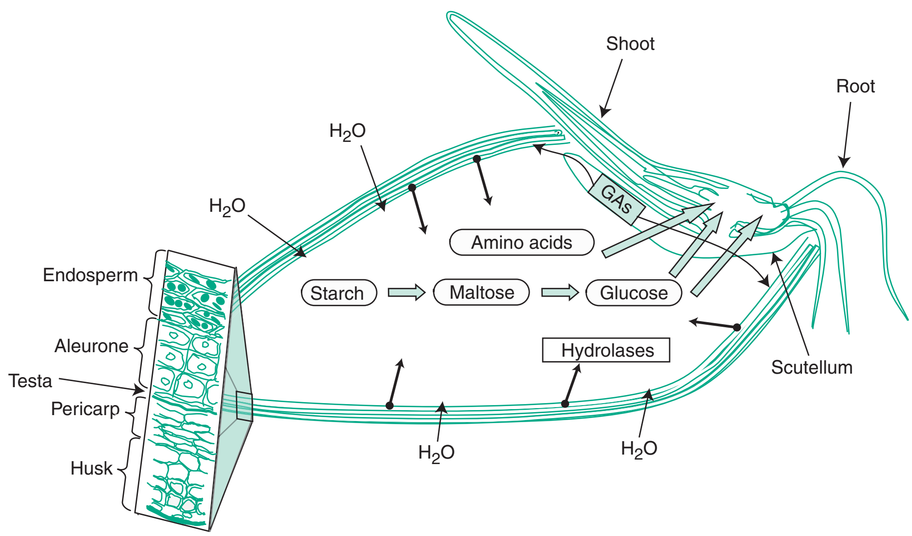

Figure 3 A generalized diagram of a germinating grain to show the various parts of a grain and the major biochemical activities during the time of germination.

(3) transport of the glucose or glucose-1-phosphate from the storage organs to the hexose-phosphate pools of developing plant cells for further metabolism into chemical constituents and energy. In germinating seeds, the initial degradation of starch granules is associated with an increase in the α-amylase activity. Intact starch granules are attacked by α-amylase resulting in the formation of random pits on the granules. During the α-amylase attack, α(1,4) bonds both in amylose and amylopectin are randomly broken to release large glucan polymers. Subsequent degradation occurs with assistance from β-amylases, phosphorylases, maltases, and starch de-branching enzymes. α-Amylase action on amylopectin, which contains both α(1,4) and α(1,6) glucan linkages, results in maltose and branched dextrins of short chain length as α-amylase cannot break the α(1,6) linkages. β-Amylases first act only on the nonreducing ends of the glucan polymer and hydrolyzes starch into β-maltose, which is rapidly converted into natural mixtures of α- and β-isomers by mutarotation. Starch phosphorylases are a group of phosphorolytic enzymes, which degrade starch molecules from the nonreducing end of glucan chain. The reaction results in complete breakdown of amylose to glucose-1-P units, but in amylopectin the degradation stops within a few glucose residues of the branch point to give dextrins. Like plant amylases, starch phosphorylases are also widely distributed in plants, and have an important role in starch degradation in leaves and seeds of many plants. However, in germinating cereal grains, starch phosphorylase activity is not detected giving the α- and β-amylases a dominant role in starch degradation. In seeds of other species and in leaves, starch phosphorylases also contribute towards starch degradation.

The α(1,6) glucan linkages in the starch molecule are hydrolyzed by starch de-branching enzymes, which have also been implicated in starch synthesis as described above. Depending upon the substrate specificity, the debranching enzymes are classified as isoamylases and pullulanases. This group of enzymes hydrolyze α(1,6) linkages, thus producing additional end groups for action by amylases and phosphorylases. Concerted action of these enzymes results in the production of maltose, glucose, or glucose-1-phosphate. Maltose rarely accumulates during starch digestion as it is broken down to glucose by maltase.

Raffinose Oligosaccharide

Stored raffinose oligosaccharides are rapidly utilized during germination. In higher plants, a α-galactosidase hydrolyzes the galactoside bonds of the raffinose oligosaccharides or other α-D-galactosides to release a galactose moiety. The galactose unit is thereafter phosphorylated by a galactokinase to produce α-D-galactose-1-P, which is further metabolized through UDP-galactose to produce either UDP-glucose or glucose-1-P, which enter the cellular hexose phosphate pool. Depending on the metabolic activities of the tissues, the carbon may flow into the respiratory pathways as in the case of germinating tissues, or to the synthesis of starch, sucrose, oligosaccharides or other cellular components such as glycolipids or glycoproteins (Figure 2) in young meristematic tissues. Most of the raffinose oligosaccharide degrading enzymes have been purified from seeds of pulse crops and increased activities have been shown to be associated with seed germination. However, strategies to

modulate the activities of raffinose oligosaccharide degrading enzymes are complicated by the presence of two distinct pathways for the metabolism of galactose-1-P to UDP-glucose and glucose-1-P.

Fructans

Fructans are hydrolyzed by β-fructofuranosidase enzymes having specificity for the β(2,1) or β(2,6) linkages. A β-fructofuranosidase from Jerusalem-artichoke tuber successively cleaves fructose units from inulin until a mixture of fructose and the terminal sucrose unit remains. Fructose can enter directly the respiratory pathway, whereas sucrose must be broken down to glucose and fructose first. In the last few years, fructan degrading exohydrolytic enzymes have been purified from many plant species. Two exohydrolytic enzymes, one with a β-(2-6)-linkage-specific fructan- β-fructosidase and another with β-(2-1)-linkage-specific activity, from *Lolium perenne* and Jerusalem artichoke, respectively, have been isolated.

Sucrose

Invertase and SS are the two enzymes capable of cleaving sucrose present in plants. Invertases catalyze the irreversible hydrolysis of sucrose to free glucose and fructose. Invertases are present in the cytosol, vacuole, and in the cell walls. The cytosolic invertase is an alkaline type, active at pH 7.5, whereas the vacuolar and cell-wall invertases are acidic enzymes active at pH 5 or lower. The cell-wall invertases hydrolyze the incoming translocated sucrose into glucose and fructose molecules for conversion into storage carbohydrates.

SS catalyzes the reversible reaction converting sucrose and UDP to fructose and UDP-glucose. Fructose is available for respiration and the UDP-glucose can enter the hexose-phosphate pool for further metabolic processes. SS, compartmentalized in the cytosol, is the main enzyme that degrades sucrose in starch-storage organs such as developing seeds or in rapidly growing tissues that are converting sucrose to cell-wall structural polysaccharides. In slow growing and mature cells, invertase is the major enzyme hydrolyzing sucrose and provides substrates for respiration.

Cell-Wall Polysaccharides

The cell-wall polysaccharides have a physiologically different role in seed germination. The process of germination and seedling development requires the participation of several endo- and exohydrolases that degrade or modify the cell-wall structure. During germination, (1,3) and (1,4)-β-D-glucan endohydrolases hydrolyze the (1,4)-linkages adjacent to the (1,3) β-D-glucosyl residues to release large oligosaccharides. The resulting oligosaccharides are further hydrolyzed by broad-specificity exohydrolases to produce glucose, which can subsequently be used in numerous ways (Figure 2). Some of the other cell-wall polysaccharides such as arabinoxylans can be degraded to oligosaccharides which subsequently follows the oligosaccharide degradation pathway as described above.

Concluding Remarks

In most grains, carbohydrates are the major components that provide energy needed during seed germination and early seedling development. Carbohydrates also play a major role in determining the quality of the grain and its subsequent use by human beings. Carbohydrate metabolism in plants differs from most other organisms as it occurs in two distinct cellular compartments, the plastid and the cytosol. Most of the biosynthetic activities take place in the plastids, chloroplasts in leaves and amyloplasts in the storage organs. The carbohydrate metabolism in the cytosol communicates with that of the plastids through metabolic carriers in the plastid envelope. The stationary nature of the plant forces it to withstand changes in the external environment and therefore has developed inherent flexibility in its metabolism to cope with both biotic and abiotic stresses. It is often found that a single reaction in carbohydrate metabolic pathways is catalyzed by multiple isoforms of an enzyme. Differences in temporal and spatial expression of genes encoding these isoforms present several challenges to modify carbohydrate metabolic pathways by genetic engineering. To date, it has been possible to alter the expression of genes encoding starch biosynthetic enzymes to produce crops with modified grain carbohydrates that have health benefits for human beings and/or grain processing advantages. Some advances have also been made in changing the cell compartment and/or tissue in which a specific polysaccharide is stored. As the understanding of the carbohydrate metabolic pathway increases, novel strategies to alter carbohydrate biosynthetic or degradation pathways will emerge, which can be utilized to develop crop cultivars with novel products in the grain. These new crops will diversify the uses of the grain to benefit both the producers and consumers.

CELIAC DISEASE

H Wieser, German Research Center of Food Chemistry, Garching, Germany

Introduction

Celiac (coeliac) disease (CD) is a permanent intestinal intolerance to dietary wheat, rye, and barley proteins (gluten) that produces mucosal lesions and nutrient malabsorption in genetically susceptible individuals. The current essential therapy is a strict lifelong withdrawal of gluten from the diet. The prevalence of CD was underestimated for a long time; with the development of sensitive serological tests, it is now becoming clear that CD is one of the most frequent food intolerances in many parts of the world. An overview of extensive research on CD is provided.

Definition

CD also known as celiac sprue and gluten-sensitive enteropathy, may be defined as an inflammatory disease of the upper small intestine (duodenum, jejunum)

in genetically susceptible individuals. CD is a permanent food intolerance induced by ingestion of storage proteins (gluten) from certain cereals (wheat, rye, barley) that causes damage of the enterocytes and, as a consequence, malabsorption of important nutritients. CD patients develop a flat jejunal mucosa with the absence of normal villi, a cellular infiltrate of the lamina propria and an increase of the number of intraepithelial lymphocytes. The mucosa improves morphologically on treatment with a gluten-free diet and relapses when gluten is reintroduced. Immediate symptoms of CD frequently include diarrhea, cramps, and pale and bulky stools. Therapeutically, lifelong gluten-free diet is necessary.

Historical Review

CD was already noted by the Roman physician Aretaeus the Cappadocien as early as the second century AD, describing that "if diarrhea does not proceed from a slight cause of only one or two days duration and if, in addition, the general system be debilitated by atrophy of the body, the celiac sprue of chronic nature is formed." However, it was not until 1888 that Samuel Gee described the classical account of CD features. He recognized that "if the patient can be cured at all it must be by means of the diet." Thereupon the dietary treatment of CD was continued more or less successfully. For example, all sources of carbohydrates such as bread, cereals, and potatoes were excluded or a banana diet was recommended. Such extreme dietary therapy was then used extensively for many years.

In 1950, WK Dicke, a Dutch pediatrician, observed a decline in CD in Holland during the grain-deprived years of the Second World War. A clear association between CD and the ingestion of wheat and, later on, of rye and barley, was established. Fractionation of wheat flour and testing led to the conclusion that gluten was toxic, whereas starch and the water-soluble albumins were not. Since that time, a "gluten-free diet" was the conventional treatment of CD, which excluded products containing wheat, rye, and barley only excepting pure starches produced from these cereals. The celiac toxicity of oats has been judged controversially up to this day.

Symptoms and Pathology

A range of symptoms may be associated with CD and these can be divided into intestinal features and those caused by malabsorption (e.g., deficiency of vitamins and minerals). In infants, classical symptoms appear after weaning and introduction of cereals into the diet: diarrhea, abdominal distension, failure to thrive, vomiting, muscle wasting, and apathy. Older children tend to have more varied symptoms, besides diarrhea or constipation features such as anemia, loss of appetite, and short stature may be predominant. Diarrhea is the main presenting feature of adults, in some patients anemia, osteoporosis, abdominal pain, loss of weight, and weakness may be found. A minor number of patients present psychological or psychiatric symptoms. Frequently, the disease may be clinically silent or masked by associated diseases like diabetes, though the patients exhibit the full mucosa lesion. They are discovered only when intestinal studies are undertaken.

The small intestinal lesion of CD has a highly characteristic morphology, but it may vary from patient to patient depending on the severity and extent of disease. Patients show a wide variation of mucosa appearance from a complete flat to a convoluted pattern. The parameters usually assessed for the measurement of intestinal mucosa are villous height, villous width, villous height to crypt depth ratio, mucosal thickness, epithelial cell height, crypt mitotic activity, and number of intraepithelial lymphocytes. Electron microscopy demonstrates fewer microvillous intramembrane particles and abnormal tight junctions between epithelial cells. In untreated CD, there are raised serologic antibodies to gliadin, reticulin, endomysium, and tissue transglutaminase (tTG).

Epidemiology and Genetics

CD is mostly a disease prevalent in Europe and those countries to which Europeans have emigrated including North and South America and Australia. However, CD is also known to occur in many other parts of the world. In former times, CD was considered a comparatively uncommon disorder with prevalence rates of 1 in 2000–1000. Several recent studies using serologic screening followed by small intestinal biopsy have shown a much higher prevalence, and it is now estimated that CD may affect 1 in 300–100 individuals. The iceberg is a common model to describe the epidemiology of CD. The tip of the iceberg is formed by patients who have been diagnosed by conducting a biopsy demonstrating a flat mucosa. Below the waterline, there is a big group of undiagnosed patients with a flat mucosa, but with no or weak symptoms (silent CD). Just at the bottom of the iceberg there is a small section of patients with a normal mucosa, but with the genetic predisposition and increased levels of celiac-specific antibodies. These subjects may develop clinically overt CD later in life (potential CD).

The occurrence among first-degree relatives of CD patients has been reported to be fairly strongly (10–15% prevalence). Concordance between dizygotic twins has been found to be in a range of 11–20% and that between monozygotic twins 70–86%. CD can occur at any age, but in adults, the peak incidence is in the fifth decade. Females are more commonly affected than males, the ratio has been suggested to be 2:1.

CD is associated with histocompatibility complex class II alleles HLA-DQ2 and HLA-DQ8. HLA-DQ2 was found in 98% of celiac patients from northern and central Europe. However, 25% of the healthy population carry DQ2 and will never develop CD. Thus, genetic factors alone do not explain the development of CD and additional factors such as infection agents and hormonal status may be involved. In southern Europe and Israel, DQ2 is also the major susceptibility genotype (92%), there is another small section who carry DQ8. The only nonHLA region to which association with CD has been convincingly shown until now is the CTLA-4/ CD28 region on chromosome 2q33.

Pathogenesis

The earliest theory on the pathogenesis of CD was based on the missing peptidase hypothesis. The basic defect was considered to be a deficiency of an enzyme in the small intestine which is required for the digestion of celiac toxic proteins. This theory was supported by studies of the celiac-active peptide fraction 9 isolated from an enzymatic digest of gluten. This fraction was only partially digested by homogenates of remission celiac mucosa, whereas it was completely digested by corresponding homogenates from normal people. Other authors, however, have shown that peptidase activities are normal in the mucosa of CD patients on a gluten-free diet. Nevertheless, the enzymatic hypothesis cannot be completely ruled out, because enzymatic activities within the enterocytes have not been studied sufficiently until now. Another theory was based on a nonimmunomediated lectin-like effect of celiac toxic proteins due to binding to glycoproteins on intestinal epithelial cells of CD patients. Carbohydrate side chains of toxic proteins were postulated to be important in activating CD. However, there was little evidence to support this because A-gliadin, a group of aggregative α-gliadins known to be celiac toxic, lacks such carbohydrate side chains. Partial sequence homology between an adenovirus E1B protein and α-type gliadins led to the proposal that human adenovirus type 12 might be an environmental factor involved in the pathogenesis of CD.

The currently accepted theory of pathogenesis is based on a primary immune response to gluten proteins as antigens and to tTG which has been identified as the autoantigen recognized by the endomysial antibodies. The antigens are regarded not to be the intact gluten proteins, but certain peptides which are formed from the proteins as a result of exposure to proteolytic enzymes of the gastrointestinal tract. The peptides are bound to the intestinal mucosa, then pass through the enterocytes by means of endo- and exocytosis and come into contact with the macrophages and antigen-presenting cells of the lamina propria. There are indications that the process is induced by a hyperimmune response in individuals with the histocompatibility antigens DQ2 and DQ8. The gluten peptides are bound specifically to these HLA molecules, processed, e.g., deamidated by tTG and presented to the T cell receptors of gluten-sensitive CD4 helper cells (Figure 1). The T cells then provide help for the production of antibodies to gluten proteins and autoantibodies to tissue transglutaminase. Simultaenously, the stimulation of T cells leads to the secretion of pro-inflammatory T helper (Th-1) cytokines, in particular γ-interferon and nitric oxide which produces premature senescence of small intestinal enterocytes, shedding of these cells and, in turn, the observed small intestinal enteropathy.

Associated Diseases

Dermatitis herpetiformis, a skin disorder, is associated with CD, because some degree of gluten-sensitive enteropathy is common to both conditions. It appears as patches of itchy red papules and blisters on the extensor surface and pressure areas; healing up results in pigmentation. Histologically, there is infiltration of the dermal papillae with inflammatory cells. The histology of the small intestine is similar to that of CD, but the abnormalities tend to be milder and more patchy. In many cases, a gluten-free diet results in a significant improvement. Recent screening studies have shown an increased prevalence of CD in autoimmune disorder such as type 1 diabetes, thyroid disease, primary biliary cirrhosis, and Sjögren syndrome. Moreover, IgA deficiency, chronic fibrosin alveolitis, and other interstitial lung diseases, concomitant distal ulcerative colitis have been reported in association with CD. In other instances, there are unexpected associations such as epilepsy and various undefined neurological disorders. A small number of patients with CD have exhibited symptoms of various psychiatric disorders, e.g., schizophrenia. A lymphoma of the small intestine is the classical malignancy associated with CD. The prevalence of carcinoma of the small intestine, esophagus, or pharynx

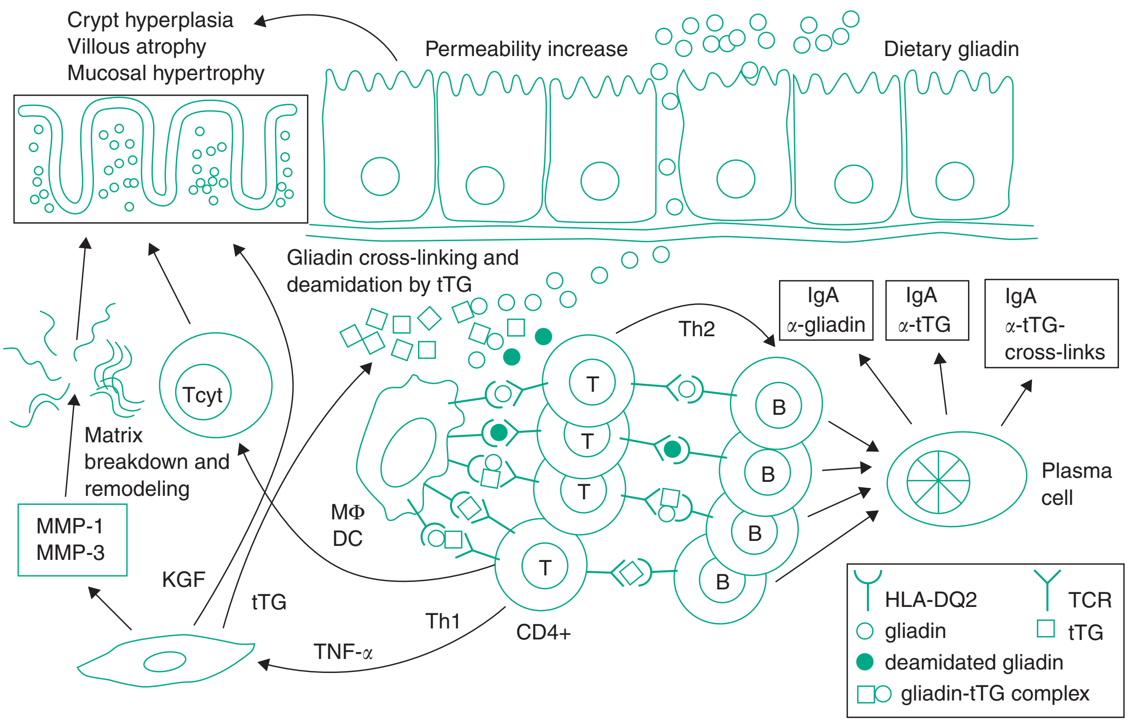

Figure 1 Immune response in the gut-associated lymphoid tissue and destruction of enterocytes in the pathogenesis of CD (B = B cell, CD4 = helper T cell, DC = dentritic cell, HLA = human leucocyte antigen, Ig = immuno-globulin, KGF = keratinocyte growth factor, M = macrophage, T = T cell, TCR = T cell receptor, TNF = tumor necrosis factor, tTG = tissue transglutaminase). (Courtesy of D Schuppan, Erlangen, Germany (previously unpublished).)

also increases with CD. It has been reported that a strict gluten-free diet helps safeguard against these malignancies.

Diagnosis

Most important for the diagnosis of CD was the introduction of small intestinal biopsies in 1960. Since that time mucosal biopsy is regarded as the golden standard for the firm diagnosis of CD. The histological examination of biopsy specimens demonstrates a flat mucosa with the absence of normal intestinal villi, a cellular infiltrate of the lamina propria, and an increase in the number of intraepithelial lymphocytes. The European Society for Pediatric Gastroenterology and Nutrition (ESPGAN) recommended three intestinal biopsies in 1970. One should be performed at the time of presentation, another after the patient has been on a gluten-free diet demonstrating improvement and the final biopsy after the patient has been rechallenged with gluten, when villous atrophy is expected to have recurred. The question of whether three biopsies and supervised gluten rechallenge are necessary has been a matter of debate. Recently ESPGAN has suggested that it is not mandatory to proceed to a gluten challenge, if a gluten-free diet has produced a good improvement in symptoms and in the morphology of the biopsy specimen. Noninvasive screening tests would be of considerable aid in diagnosis, but cannot replace histology. In untreated CD, there are enhanced antibodies to gliadins, reticulins, endomysium, and tTG (Figure 1). IgA antigliadin antibodies have a sensitivity of ~80–90% and a specificity ~85–95%. IgG antigliadin antibodies are less sensitive and specific. Until recently the determination of IgA antiendomysial antibodies was the most important test in the diagnosis of CD reading sensitivity and specificity ~97%. The combination of antigliadin and antiendomysial antibodies has positive and negative predictive values approaching 100%. The recent demonstration that the antigen for endomysium is tTG has allowed the development of an enzyme-linked immuno-sorbent assay (ELISA) for both IgG and IgA tTG. They are similar in sensitivity and specificity like the endomysial antibody test, but they are cheaper and their results are much easier to reproduce.

Therapy

After a diagnosis of CD has been established, permanent withdrawal of gluten from the diet is the current essential treatment. Gluten-free diet involves avoiding products containing wheat, rye, and barley. Starches

of these cereals are permitted, when the nitrogen content does not exceed 0.05% (Codex Alimentarius Standard 1981) or the gluten level is lower than 200 mg per kg (Draft Revised Codex Standard 2000). The daily intake of gluten should not exceed 20 mg. The toxicity of oats has been discussed controversially. Recent studies have, however, provided strong evidence that oats do not damage the mucosa of CD patients. Since small amounts of gluten are hidden in many foods, dietary counseling is absolutely necessary. In most countries celiac societies are an invaluable help in providing dietary guidelines and food lists. Keeping a strict gluten-free diet most patients show a rapid clinical response with improvement of symptoms within weeks. Histological improvement is slower and complete recovery can take months or years. The prognosis for patients who are correctly treated is excellent. Failure to implement a strict diet may result in continuing symptoms and in the two major complications of osteoporosis and malignancy.

CD patients consume gluten-free food from two different categories. First, they are allowed to eat a wide range of common products such as meat, fish, milk, fruits, and vegetables. In the case of composite foods, however, it is difficult to recognize whether they are gluten free or not. An informative labeling of gluten as an "allergen" is currently discussed in the framework of Codex Alimentarius and in the European Union. Second, patients consume dietetic food that is gluten free according to the Codex Alimentarius Standard. The new standard draft proposes a gluten level of 20 mg per kg dry mass for naturally gluten-free food and 200 mg per kg for food rendered gluten free such as wheat starch. For gluten analysis, extraction with 60% ethanol and an immuno-chemical method for quantitative determination (ELISA with mono- or polyclonal antibodies) are recommended. Dietetic gluten-free foods are mostly substitutes of products usually containing wheat, rye, and barley such as bread, other baked products, pasta, and beer. Common basic materials used for these products are flours from maize, sorghum, rice, buckwheat, or chestnut, and common thickening agents are locust bean gum or guaran gum.

Toxicity Testing

Most investigators would agree that *in vivo* testing is the "gold standard" for assessing CD toxicity of proteins or peptides. Early workers established toxicity in a series of feeding tests based on the production of symptoms such as steatorrhea or on tests such as malabsorption of fat or xylose. However, an important impediment was that CD patients differed widely in their sensitivity to gluten and consequently, the optimal amount of gluten equivalent used to challenge patients and the duration of challenge were uncertain. In any case, 10–100 g of gluten equivalent were necessary for the testing of each patient and such large amounts were the most crucial limiting factor for the feeding tests of purified proteins or peptides.

By direct instillation into the small intestine followed by biopsy, the required amounts could be reduced to 1 g equivalent of gluten. Some of the histological changes of the mucosa have been noted as early as 2 h from the beginning of instillation. Similarly, mucosa of CD patients is sensitized to gluten and offers a more convenient approach for investigative and diagnostic purposes. One to two hours after challenge with 2 g gluten equivalent, mucosa showed significant swelling of the lamina propria, a rapid fall in most cells, and a marked rise of intraepithelial lymphocytes. Because *in vivo* tests require relative large quantities of substances and only a limited number of test patients are available, a series of *in vitro* tests has been developed. The organ culture of human small intestine, which requires only milligram equivalents of gluten, has been proposed as providing the most reliable *in vitro* approach. The intestinal tissue from patients with active CD is removed as a part of the diagnostic procedure and incubated in a culture medium. The tissue shows improvement of enzyme activity and morphology in the medium alone, but not in the presence of CD toxic substances. Apart from human material tissue cultures with fetal rat and chicken intestine have been used. Assays based on the stimulation of peripheral blood lymphocytes, the production of the leukocyte-migration inhibition factor or macrophage proagulant activity, the agglutination of leukemia K562 cells, and the disruption of rat liver lysosomes have been applied for screening tests. However, *in vivo* testing ultimately will be necessary to evaluate conclusions on *in vitro* testing.

Toxicity of Cereal Proteins

The relationship between CD and the ingestion of wheat flour was established in 1950. Soon after, a series of investigations led to the conclusion that rye and barley were also harmful, whereas maize, rice, buckwheat, and potatoes were not. There has been disagreement about the toxicity of oats; the reason for that could have been that commercial oat flour is frequently contaminated with small amounts of wheat, rye, or barley. Recent studies, however, indicated that pure oats do not activate CD. Accordingly, CD is closely related to the taxonomy of cereals: only species found in the tribe Triticeae within the grass

family Poaceae are likely to exacerbate CD. All wheat species besides bread wheat such as durum wheat, spelt, emmer, einkorn, and kamut has been proposed to be toxic for CD patients.

Immediately after wheat was established as the CD activating cereal, fractionation of the flour and *in vivo* testing led to the conclusion that gluten is toxic, whereas starch and albumins are not. Gluten is the rubbery protein mass that remains when wheat dough is washed with water to remove starch granules and other soluble constituents. By its cohesive viscoelastic properties gluten to a large extent determines the unique baking quality of wheat. Gluten proteins can be divided according to their solubility in aqueous alcohols into the soluble gliadins and the insoluble glutenins. Toxicity tests indicated that the gliadin fraction was the most toxic factor, whereas the effect of the glutenin fraction was described either nontoxic, weakly toxic, or as toxic as gliadins, but on a very inadequate evidence. The reason for this disagreement could be that glutenin preparations isolated from wheat flour or gluten have been differently contaminated by gliadin components covalently bound to the glutenin aggregates.

Flour protein fractions of rye and barley have not been tested for celiac toxicity until now, but equivalent to the gliadin fraction of wheat, the corresponding prolamin fractions of rye (secalins) and barley (hordeins) were associated with CD. Although the prolamin fractions of cereals are crude mixtures of different proteins, their amino acid compositions show a close relationship to both taxonomy and celiac toxicity (Table 1). Toxic gliadin, secalin, and hordein fractions are characterized by the highest contents of glutamine (35–37 mol.%) and proline (17–23%). Both amino acids have been considered to be important for CD toxicity. The prolamins of rice, millet, and maize are lower in glutamine and proline, but rich in alanine (9–14 mol.%) and leucine (12–19 mol.%). Oats are in a medium position, the glutamine content being similar to the Triticeae prolamins and the values of proline and leucine in agreement with those of other species.

Among the prolamin fractions, only gliadin from wheat has been investigated in detail. The digestion with pepsin and trypsin alone or followed by pancreatin resulted in the retention of toxicity, and a peptide mixture with a molecular mass less than 1000 was still toxic. Also, the breakdown of the disulfide bonds by oxidation or heating during the baking process did not destroy toxicity. In consequence, the three-dimensional structure of gliadin proteins is not important for the toxic effect. The complete degradation into free amino acids by acid hydrolysis, however, rendered it harmless, as did extensive deamidation of glutamine side chains with a limited cleavage of peptide chains. Among the different gliadin types (α-, γ-, and ω-gliadins), A-gliadin, a well-defined small group of aggregable α-type gliadins, was shown first to be toxic by instillation into small intestine followed by biopsy. Subsequent *in vivo* and *in vitro* studies demonstrated that all gliadin types produce toxic effects. In contrast, the major protein types of the glutenin fraction, high-molecular-weight (HMW) and low-molecular-weight (LMW) subunits have not been tested *in vivo* until now. Recent studies demonstrated an intestinal T cell response to TG-deamidated HMW subunits of glutenin.

Only few attempts were made to detoxify gluten, namely by enzymatic treatment; whereas the digestion of gluten by pepsin, trypsin, and pancreatin resulted in the retention of toxicity, further digestion with fresh pig intestinal mucosa rendered the preparation nontoxic. By another study, the toxic action of gluten was eliminated by crude papain, but not after digestion with pure papain. The crude papain used was found to contain a deamidase which liberates free ammonia from gluten. Recently an endopeptidase derived from the bacterium *Flavobacterium meningosepticum* was demonstrated to cleave the normally resistant proline-rich region of α-gliadins corresponding to a 33 amino acid fragment. Accordingly, the T cell activating properties of the peptide was rapidly diminished by the enzyme. The authors suggested a strategy for oral peptidase supplement therapy for CD.

Toxicity of Peptides

Because gliadin could be partially hydrolyzed by enzymes without loss of toxicity, further investigations were focused on the testing of peptides. The introduction of *in vitro* test systems, in particular the organ culture test, enabled the detection of toxic compounds in milligram and even microgram amounts. Pure peptides were isolated from enzymatic digests of whole gliadin and A-gliadin by different separation techniques. A dodecapeptide corresponding to residues 75–86 of α-gliadins and isolated from a peptic tryptic pancreatic digest of gliadin was shown to be effective on fetal chick intestine and on rat liver lysosomes. Organ culture tests with tissues from CD patients revealed that peptides corresponding to the residues 1–30, 3–55, 3–24, 25–55, and 31–55 of α-gliadins were toxic. Peptides corresponding to the residues 56–68 and 247–266, however, were inactive. Altogether the results indicated that regions from the N-terminal domain of α-gliadins are involved in the pathogenesis of CD. They are characterized by high contents of glutamine and proline, and the tetrapeptide sequences PSQQ and QQQP common for the toxic peptides have been considered as key sequences for further studies. β-Turn conformations of the peptides has been suggested to contribute to toxicity.

Since 1987, a panel of synthetic peptides containing sequences of gluten proteins has been tested using *in vitro* and *in vivo* systems. In the following the results of instillation (*in vivo*) and organ culture tests (*in vitro*) are summarized (Table 2). Five synthetic peptides derived from α-gliadin sequences were tested both *in vivo* and *in vitro*. Peptides α 31–43, α 31–49, and α 44–55 were found to be toxic and peptides α 3–21 and α 202–220 were not toxic. Peptides comprising alanine-substituted variants of peptide 31–49 remained toxic in some patients when residues L31 and P36 were substituted, but lost toxicity when residues P38, P39, and P42 were substituted. In further *in vivo* studies, peptides α 206–217 and α 56–75 were toxic, whereas the shortened peptide α 56–68 turned out to be inactive. Although the investigations described were somewhat unsatisfactory with regard to both number of tests and purity of peptides, it could be concluded that regions of most toxic sequences of α-gliadins occur in the repetitive N-terminal domain and consist mainly of glutamine, proline, and aromatic amino acids. Corresponding repetitive sequences of γ- and ω-gliadins fit well into the potentially toxic sequences of α-gliadins, whereas the repetitive sequences of LMW and HMW subunits of glutenin show significant differences.

Recently, a number of intestinal T cells from CD patients have been studied in order to determine the stimulation capacity of gluten peptides. A selection of such peptides is presented in Table 3. Several stimulatory epitopes were found in α- and γ-gliadins that are mostly located in the glutamine and proline rich N-terminal domain. With one exception (γ 60–79), the peptides were barely stimulatory in an untreated form, but became stimulatory by deamidation after acid-heat or tTG treatment. Studies of peptides from the N-terminal domain of α-gliadins demonstrated that the deamidation of a single glutamine residue at position 65 was critical for T cell recognition. Such negatively charged residues were proposed to be preferred in positions 4 and 6 of the antigen binding grove of HLA-DQ2 molecules. Modification

of single positions with an alanine residue indicated that the sequence region 63–71 was essential for the stimulatory effect. T cells of CD patients recognized also natural peptic fragment of the C-terminal domain of α-gliadins. The smallest active peptides included the residues 226–237 and 227–238, respectively. Deamidation of glutamine residues was not necessary for the stimulatory effect. By combining high-performance liquid chromatography (HPLC) and mass spectrometry peptides from digested gluten derived from LMW and HMW subunits of glutenin were also identified as activating T cells from CD patients. The effect of deamidation by tTG has been shown to be heterogeneous and can be positive, neutral, and negative. Altogether, numerous immunodominant peptides from gluten have been identified and much more epitopes are thought to exist. These *in vitro* experiments with isolated T cells pose a lot of questions, regarding the relations between the amino acid sequences and the stimulatory effects, the extent to which the stimulatory peptides reach the small intestinal mucosa after exposure to gastric and duodenal proteases and if these peptides are responsible for toxicity leading to enteropathy. Up to now *in vivo* toxicity of peptides able to stimulate T cells has been proven in only one case (peptide α 56–75, Table 2).

Future Prospects

Research work will continue on full characterization of all epitopes within proteins from wheat and related cereals that exacerbate CD. Recombinant proteins produced by transgenic microorganisms will aid these investigations. Analytical systems for the detection of such epitopes in foods for CD patients will be advanced in terms of their specificity and sensitivity. Scientific knowledge about the molecular mechanism of CD will increase step by step and facilitate the development of therapies, for example, based on immuno-modulation or the application of specific enzymes for detoxification of proteins. Wheat, rye, and barley proteins might be modified by gene engineering to CD inactive epitopes without loss of their wished functionality as bread-making properties of wheat.

CEREALS

Contents

Overview

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The cereal grains are defined as "flowering plants of the Grass Family (Poaceae or Gramineae), whose seeds are used as food." The name "cereal" derives from Ceres, the Roman goddess of grain. Colloquially, the word "cereal" has also come to refer to the range of breakfast foods, e.g., corn flakes, made from the cereal grains. The words "seed," "kernel," or "caryopsis" are also used to denote the cereal grain. In addition, the term "corn" is sometimes used for the grains of the cereal species in general, but more often "corn" denotes the cereal species maize, also known as "Indian corn." A wheat seed is shown in Figure 1, as it appears by scanning electron microscopy.

The cereal grain serves two contrasting functions.

1. For the plant, the mature grain is solely of significance as a seed, namely, the means by which the species is perpetuated. When the plant has died, the ongoing life of the cereal seed is in its embryo or germ (Figure 2) (*see* **Grain, Morphology of Internal Structure** and **Grain and Plants, Morphology**). Most of the grain's mass is taken up by the endosperm, which is the storage organ of the grain. It contains the starch and protein for the "rainy day" when moisture will trigger the dormant seed to start swelling and producing roots and a shoot. In that situation, the endosperm provides the

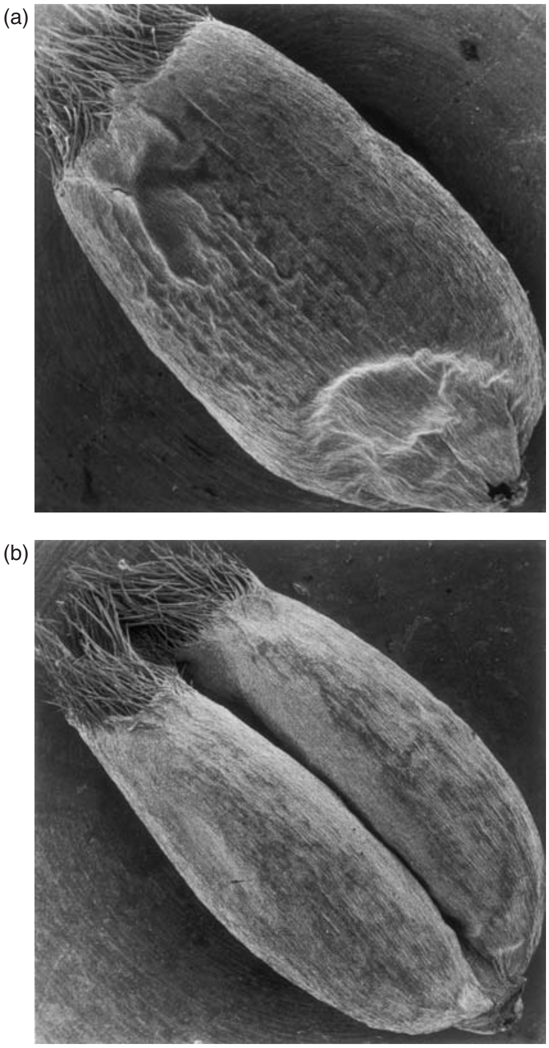

Figure 1 The wheat grain, showing the "brush" at the end opposite from the point of attachment ("hilum") to the wheat head. The "crease" extends along the ventral side of the grain, opposite to the dorsal (top) where the germ is located at the hilum end. These images were provided by scanning electron microscopy, with the grain resting on the stage of the microscope. (Reproduced with permission from Wrigley CW (2004) Cereal Sprouting. In: Goodman RM (ed.) *Encyclopedia of Plant and Crop Science*. New York: Marcel Dekker.)

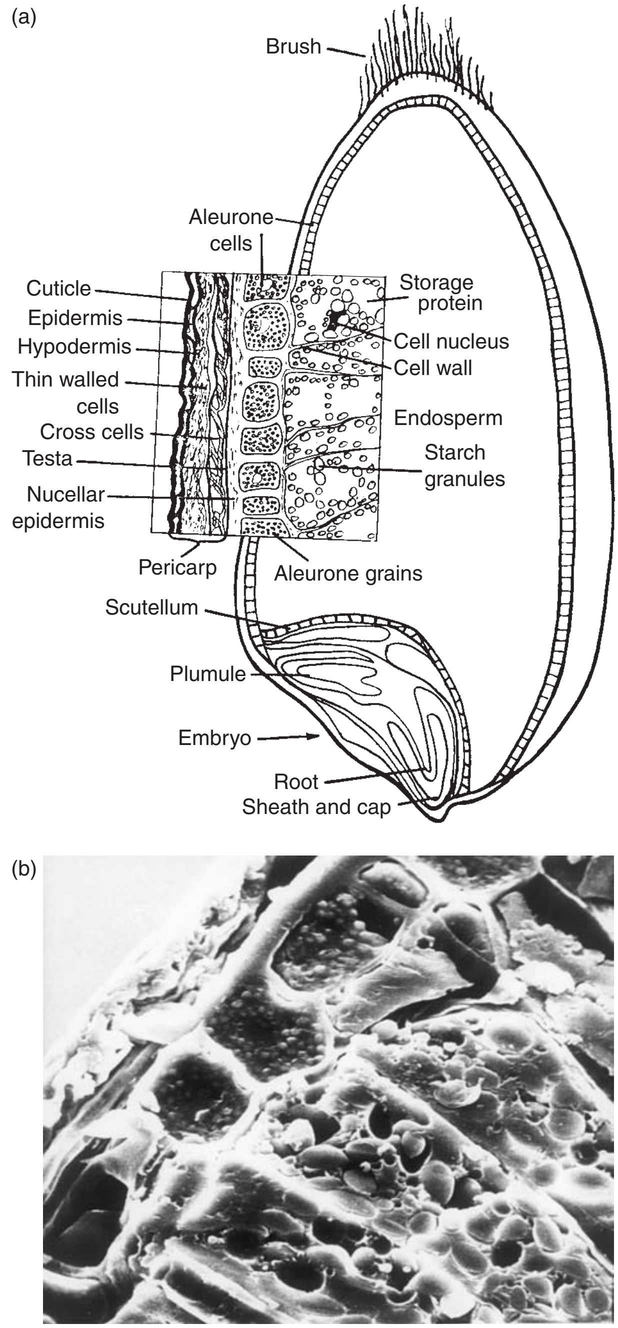

Figure 2 Diagram of the many parts of a wheat grain, cut in half to show its subcellular structure, plus electron microscope image of the cut surface of the wheat grain.

essential nutrients for germination before the emergence of the green leaf, allowing photosynthesis to take over as the source of energy and nutrients.

2. For mankind, the mature grain is mainly of significance as an important source of nutrients, namely, an item of food for humans, and a source of feed for man's animals. Examples of these many processed foods are shown in Figure 3.

The major cereal grains of economic importance are the cool-season crops – wheat, barley, oats, and rye – and the warm-season cereals – rice (paddy), maize (corn), sorghum, and millet. Table 1 lists their botanical names and major uses. The cereals are monocotyledonous plants, as distinct from the dicotyledonous members of the wider family of grains (*see* **Taxonomic Classification of Grain Species**). The dicot grain species include the oilseeds and the pulses (grain legumes) (*see* **Oilseeds, Overview. Pulses, Overview**). The major oilseeds are canola/rapeseed, sunflower, safflower, and

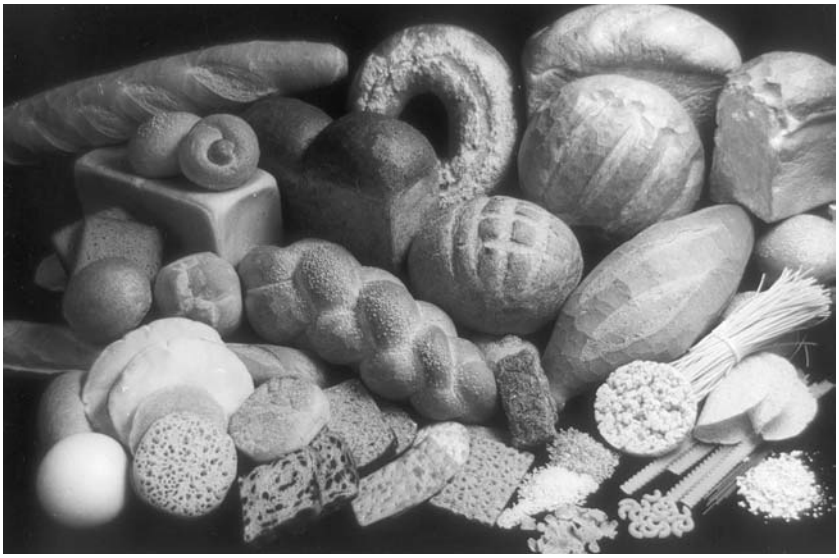

Figure 3 Some of the many foods made from cereals.

Table 1 The cereal-grain species (in taxonomic groups) and their uses

Common names	*Genus and species*	*Uses*
Pooids		
Common wheat	*Triticum aestivum*	Breads (leavened and unleavened), noodles, breakfast cereals (processed porridge), cakes, cookies, chapatis, snack foods, bulgur, ingredients for a wide range of foods, animal feed, industrial uses
Durum wheat	*Triticum turgidum* subsp. *durum*	Pasta (e.g., spaghetti, macaroni)
Rye	*Secale cereale*	Bread (often together with wheat), crispbread, spirits
Triticale	*Triticosecale*	Bread (often together with wheat), animal feed
Barley	*Hordeum vulgare*	Malt, beer, spirits, porridge, cooked grains (e.g., soup ingredient)
Oats	*Avena sativa*	Porridge (as rolled oats, oatmeal), muesli, oatcakes, animal feed
Oryzoids		
Rice	*Oryza sativa*	Cooked and fried grain, sake, extruded snack foods
Wild rice	*Zizania aquatica*	Cooked grain
Chloridoids		
Tef, Indian millet	*Eragrostis tef*	Cooked grain, porridge
Finger millet	*Eleusine coracana*	Cooked grain, porridge
Panicoids		
Corn (maize)	*Zea mays*	Polenta, breakfast cereals, tortilla, cornbread, porridge, snack foods, a wide range of industrial uses (e.g., corn syrup, food ingredients)
Sorghum	*Sorghum bicolor*	Animal feed, cooked grain, porridge, beer, flat cakes
Pearl millet	*Pennisetum glaucum*	Cooked grain, porridge
Common millet	*Panicum miliaceum*	Cooked grain, porridge
Japanese millet	*Echinochloa* species	Cooked grain, porridge
Foxtail millet	*Setaria italica*	Cooked grain, porridge

linseed (*see* **Canola**: Genetics and Breeding; Agronomy; Harvest, Transport, and Storage; Processing. **Sunflower**). The pulses include lupins, peas, beans, soybeans (also an oilseed), and cottonseed (family Malvaceae) (*see* **Beans**. **Cottonseed**. **Lupin**: Overview; Breeding; Agronomy. **Nutrition**: Soy-Based Foods. **Pea**: Overview. **Soybean**: Germplasm, Breeding, and Genetics; Agronomy; Grading and Marketing; Processing; Soy Concentrates and Isolates; Soy-Based Fermented Foods). Amaranth, buckwheat, and quinoa are other dicot grains (*see* **Amaranth, Buckwheat, Quinoa**).

Morphology of the Cereals – What They Look Like

Cereal grasses have narrow leaves, hollow jointed stems, and spikes or clusters of membranous flowers (*see* **Grain, Morphology of Internal Structure** and

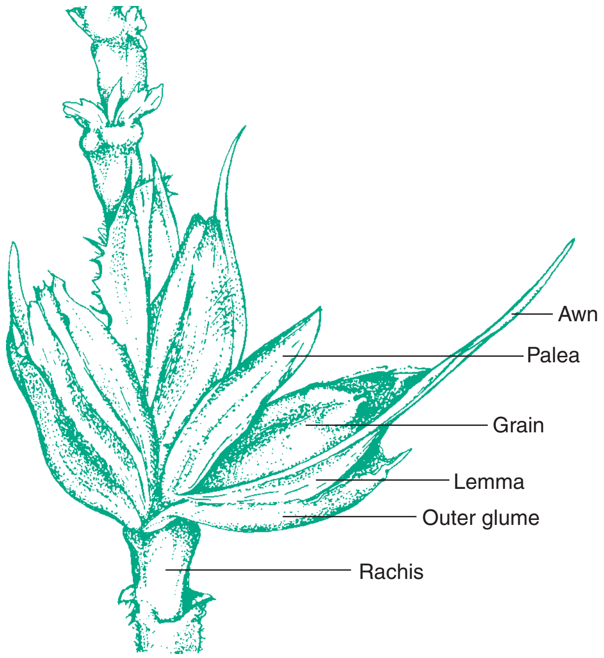

Figure 4 A spikelet of wheat, with the mature grain, held within glumes, and attached to the rachis. Other spikelets have been removed from the rachis for clarity. (Reproduced with permission from Fitzsimmons RW, Martin RH, and Wrigley CW (1983a) *Australian Wheat Varieties: Identification According to Growth, Head and Grain Characteristics*, 2nd edn., p. 13. Melbourne: CSIRO.)

Grain and Plants, Morphology). Figure 4 shows how the mature grain of wheat is held within glumes on the single stem of the head (ear). The threshing process at harvest separates the wheat grain (as in Figure 1) from the glumes, rachis, and other parts of the plant. The structure of the barley head is similar to that of wheat (Figure 5), but on threshing, the glumes of barley remain with the grain, whereas the wheat grain threshes free from the glumes. The rye grain also threshes free of the glumes. The flowers of oats and rice, on the other hand, are arranged in an inflorescence called a panicle (Figure 6). The grains of oats and rice do not thresh as the free seed. The term "groat" applies to the oat seed with the glumes removed. The term "paddy rice," or just "paddy," refers to the rice grain with its husks in place, the form in which it is harvested. The familiar cob (ear) of corn (maize) is distinct from the seed-bearing structures of the other cereals described above (Figure 7).

World Production of the Cereals

Cereal grains are grown extensively in all continents, with the obvious exception of Antarctica. They are the major sources of food for mankind, especially in developing countries. In addition to their use as

Figure 5 Heads of wheat (left), of two-row barley (center), and of six-row barley.

a major source of feed for animals, the cereal grains are extensively processed industrially for food and nonfood products. World production and trade in the major cereals are provided in Tables 2–4 for the year 1999. The provision of such data for one harvest year permits direct comparison between cereals and countries, but it should be regarded as a "snapshot" of production and trade, because of the fluctuations that occur from one year to another. Nevertheless, the tables illustrate the regional distribution of centers of production for the prominent cereals, namely, tropical countries for rice and maize, cooler regions for oats, barley, and rye.

World production of all cereal grains approaches 2 billion tons per year on average (including rice as paddy, unmilled). This represents ~700 g of grain per person per day for the world's population, assuming that all the cereal grain could be used for food, and assuming that it could be transported to all the regions where it is needed. Of course, this is neither practicable nor possible, since many of the regions of production are distant from the places of need. In addition, the world's agricultural and industrial operations are reliant on significant amounts of cereal grain.

On average, world production of wheat totals ~600 million tons (Mt) annually, grown on some 230 Mha, with a world average yield of ~2.6 t ha^{-1}. Most of this production is used in the countries in which it is grown. Two-thirds of this production is used for food; the remainder goes to a combination of seed use, animal feed, and industrial processing. Many countries produce much more than their domestic requirements, resulting in world trade of ~100 Mt annually (Table 4). The main exporting regions are USA, Canada, Europe, Australia, and Argentina. Wheat's close relative, rye, is minor by comparison; world rye production is ~20 Mt annually, the main production regions being in eastern parts of Europe, especially Poland, Germany, and Russia.

World production of rice is nearly as great as that of wheat, if the production of unmilled paddy rice is considered. On the basis of milled rice, annual world production averages ~400 Mt (Tables 2 and 3). International trade for rice is much less than that for wheat and maize (Table 4). Rice, together with maize, provide the major energy and protein source for many cultures. Annual production of maize is similar to that of wheat. Statistically, maize is included in "coarse grains," production of which totals 900 Mt annually, harvested from over 300 Mha. World trade in coarse grains is ~100 Mt. In addition to maize, coarse grains include barley (averaging ~150 Mt annually), sorghum (50 Mt), and oats (30 Mt).

of civilization involved the enormous step of primitive mankind discovering that it was possible to remain in one place where cereal seed, sown intentionally, would yield a reasonably reliable source of food. As a result, people found that a fixed dwelling place could be established near the cereal crops. Further consequences were the development of permanent forms of housing, the domestication of animals (fed with the cereal grain), and the spare time to develop the many other characteristics of civilization.

Early consumption of the cereals involved merely chewing the raw grain. Then followed the primitive forms of processing, such as grinding the grain between stones and soaking the grain in water to make it easier to chew. Next, heat was discovered as a further means of easing mastication and digestion, producing a porridge or gruel. Placing a stiff porridge in the hot ashes of a fire would have made it more palatable, resulting in baked foods. A porridge left overnight would gain wild yeasts, leading to the discovery of leavening as a means of making the baked product lighter. Further refinements would have been the sieving step, to remove husks and bran particles after grinding, and the identification of wheat as the ideal grain for the baking of leavened bread.

Figure 8 Chinese steamed bread.

There is archeological evidence that primitive baked products were being made in the late stages of the Stone Age. Purpose-built ovens were used in ancient Egypt as far back as 2700 BC, with reasonably sophisticated milling and baking a millennium later. As a result of this long history of cereal-grain use, diverse uses have been developed worldwide for their processing, taking advantage of the specific characteristics of the individual cereal species (see Table 1 and Figures 3 and 8).

The Diversity of Cereal Grains

Wheat

Wheat is prominent among the cereals, because of its unique dough-forming properties (*see* **Wheat**: Genetics; Breeding; Agronomy; Harvesting, Transport, and Storage; Grading and Segregation; Dry Milling; Marketing; Wet Milling). These viscoelastic characteristics are due to the gluten–protein complex (*see* **Cereals**: Protein Chemistry), formed from the major storage protein of its endosperm. This is the basis of man's attraction to wheat – the reason for the annual cultivation of over 10^{14} wheat plants – because wheat gluten alone can sustain man's desire for leavened bread products. Major countries involved in production and trade are listed in Tables 2–5.

Ideal wheat-growing climates are temperate, with mean summer temperatures of ~15°C, an annual rainfall of 300–700 mm, falling more in spring (during grain filling) than in summer (providing opportunity for a dry harvest). Nevertheless, the climates in which wheat can be grown vary greatly, as is exemplified by wheat growing in North and Central America. In northern parts of Europe and USA, winter wheats are sown in autumn, to lie under a snow cover throughout winter, ready for the warmth of spring to bring them back into growth and grain production.

On the Canadian prairies and the northern US plains (North Dakota and Montana), the winters are too harsh to permit the growing of the higher yielding winter-habit wheats. In these very cold regions, spring wheats are sown after the snow has melted, as soon as it is possible to access the fields in spring. Thereafter,

there is very rapid growth, permitting the grain to mature for harvest just before the snows of autumn. By contrast, wheat growing in Kansas, USA, and down into Mexico may involve the likelihood of heat stress in the late stages of grain filling. Wheat growing in parts of Mexico and the Indian subcontinent involves regions of high altitude.

Yields of wheat vary considerably, depending on the rate of input of fertilizers, and especially on access to water. Some regions where high inputs are possible have "Ten-Ton clubs," involving groups of growers, who regularly achieve yields of over 10 t ha^{-1}. By contrast, regions of dry-land farming may reckon on little more than 1 t ha^{-1}. Drought and disease may reduce yields in either of these extreme cases (*see* **Cereals**: Grain Diseases. **Plants**: Diseases and Pests. **Wheat**: Agronomy).

Many factors determine the times of harvest in the various wheat-growing regions of the world, listed in Table 6. Harvest generally coincides with summer, thus reflecting whether the particular country is in the northern or southern hemisphere. Other factors include sowing date and the maturity of the particular variety sown, plus constraints such as avoidance of extremes of climate – both very cold and very hot.

There is a great diversity of uses of wheat (Table 1), such as pan breads, pocket (Arabic) breads, noodles, and steamed breads (Figures 3 and 8). In addition, there is a diversity of processing methods, especially for leavened bread. There is thus the need to breed a range of wheat varieties to suit the various processing specifications. In addition, there is the need for the appropriate variety to be grown in a suitable climate and region, with the right management, aimed at achieving target attributes of bulk density, lack of defects and contaminants, grain hardness, protein content, milling quality, and dough-forming properties. It is usual to segregate wheat after harvest into specific grades, each being suited to appropriate uses and prices. These grades carry through into world trade, forming a basis for buyers to select based on the combination of quality and price.

Table 6 Harvest times around the world for wheat

Country	*Harvest dates*
Argentina	November–January
Australia	October–January
Canada	July–September
China	May–September
England	August–September
France	June–July
India	February–May
Italy	June–July
Russia	July–September
USA	May–September

Durum, a distinct species of wheat (Table 1), has a harder, larger grain, with a yellowish hue ("amber" according to the title of the international durum grade). Because its endosperm is so hard, it fragments on milling into particles larger than does common wheat. This coarse flour ("semolina") is suited for pasta manufacture (extruded from a relatively dry dough), and also for couscous, frike, and bulgar (also known as "bulghur" or "burghul"). Some of these foods are also made from common wheat in some regions.

Rice

Like wheat, rice is another cereal with a special place in man's diet, providing a dietary staple for over half of the world's population, thus constituting their major source of energy and protein. Unlike other cereals, rice is consumed as the whole grain, after removal of the bran layers (*see* **Rice**: Genetics; Breeding; Chinese Food Uses; Wildrice, Zizania). Rice can be grown under a wide range of climates, either in flooded irrigation or under dry-land conditions. Some 90% of the world's rice production is in Asia, especially in developing countries. International trade in rice accounts for only ~4% of world production. Prices vary greatly depending on the type of rice. For example, Basmati scented rice from Pakistan and north-west India might command 4 times the domestic price of "ordinary" rice. Quality grades of rice are partly based on dimensions – long-, medium-, and short-grain rice. Quality attributes relate to the milled grain: shape, color, translucency, and uniformity, and also the absence of broken grains.

For human consumption, paddy rice is de-hulled and milled to remove the bran layers, leaving the familiar lustrous, white grain. Brown rice, much less popular for eating, retains the bran layers, together with added nutrients. Short-grain varieties (*indica* types) usually become sticky on cooking, a characteristic that is preferred in many parts of north Asia. There is a preference in many western countries for the drier, flaky quality usually provided by the long-grain varieties (*japonica* types). Whereas milled rice is mainly consumed as the cooked grain, there are also many food products made from rice, namely, parboiled rice, rice crackers and noodles, rice cakes and snack foods, rice flour, and fermented drinks (sake and rice wine).

Maize (Corn)

Maize, indigenous to the Americas, is produced worldwide – mainly in tropical and warm regions (Table 1). It is an annual plant with an erect, leafy stalk. The ear consists of a central pithy section

(the cob, Figure 7), via which nutrients are transported from the leaves and stalk to the grains (some hundreds or up to one thousand grains per cob). The tassels of the immature cob constitute the inflorescence bearing the male flowers.

There is a wide range of types of grain (*see* **Maize**: Genetics; Breeding; Quality Protein Maize; Dry Milling; Wet Milling; Foods from Maize). Variations in grain types include size, color, and hardness. Colors range from white, through yellow to red. Endosperm types include soft and floury, through to hard and flinty. Popcorn is a special type of endosperm that expands suddenly on heating, due to vapor expansion inside the grain. Sweet corn, with an unusually high sugar content, is generally harvested immature, retaining a high water content to provide the familiar juicy mouth-feel.

There is extensive industrial processing of maize, especially in the USA and Europe. An important product is a range of breakfast cereals and snack foods. Industrial processing also involves fractionation of the maize grain by wet milling into its major chemical components. The main product of processing is cornstarch, which is the largest component of the corn endosperm. By-products are maize oil, from the germ and the protein fraction, which is traded under the inappropriate term "corn gluten." These direct products may be further processed, especially the starch, much of which is hydrolyzed to simple sugars as a sweetening agent, as well as being used to make syrups and spirits.

Barley

The main uses of barley are for animal feed and for the production of malt and beer (Table 1) (*see* **Barley**: Genetics and Breeding; Agronomy; Harvesting, Storage, and Transport; Grading and Marketing; Milling and Processing; Malting). These two uses form the basis of the two main grades for trade in barley (feed and malting barley). Another major distinction is based on head morphology, namely, "two row" or "six row" depending on whether there are grains in the full set of florets in the head (six row) or there is only one set of grains on either side of the head, with the other florets sterile (Figure 5). In some barley-growing countries (Europe and Australia), six-row barley varieties are often of feed quality, but six-row varieties are used for malting in North America.

Barley is the grain used for Scotch and Irish whisky. In addition, a small proportion of the barley crop is used directly for human consumption; after pearling to remove the adhering lemma and palea, the barley grain is boiled in soup as the whole pearled grain, or it is coarsely ground and cooked as gruel. Barley flour is also used for a range of baked products, but barley is not suitable for the production of leavened bread. Nevertheless, barley appears to have been used for bread making by ancient civilizations. Barley, for example, appeared on Greek coins several centuries BC, and it was the staple diet of Roman gladiators, who were thus known as *hordearii* (reflecting the origins of the genus name, *Hordeum*).

Oats

Oat plants thrive in temperate climates, with cooler moister conditions, compared to other cereals (Tables 1–3). Oats are often used as fodder for stock, grazing off the growing plants. In such cases, it may also be possible for the farmer to harvest a crop of grain, and often this also is used on-farm as stock feed. In addition, oats are grown as a grain crop, generally using varieties that have been bred specifically for use as grain. A large proportion of harvested oats is used for animal feed, especially for horses.

Compared to the other cereal grains, the oat grain tends to have higher contents of protein, lipid, and soluble fiber (β-glucan). Oats are reported to have beneficial hypocholesterolemic properties, as well as being useful in the management of the insulin response in diabetics. For human consumption, the adhering glumes are abraded from the oat grain. The resulting groat is cut, rolled, or ground to yield products such as oatmeal, rolled (flaked) oats, and oat flour, for processing into "instant oats" for porridge, oat cakes, breakfast cereal, and infant foods (*see* **Oats**).

The groat has a higher content of lipid (fats) than wheat, plus significant lipase activity (fat-splitting enzyme), and these factors must be taken into account in oat processing. There is the consequent risk that after milling, fat rancidity, bitterness, and a soapy taste will be produced by the actions of various endogenous enzymes, namely, lipase, lipoxygenase, and peroxidase. To prevent this, it is usual for milled oats to undergo some form of heat treatment to inactivate the lipase activity. This is often done by steam treatment, together with kiln drying.

Rye and Triticale

Rye is the only cereal grain that approaches wheat with respect to bread-making properties, although the achievement of bread quality in rye breads usually requires the incorporation of a considerable proportion of wheat flour (Table 1). Rye is most popular human diet in Europe. The production of rye in Germany exceeded that of wheat from about 1940 to 1960, but more recently the production of wheat has increased considerably, and a higher

proportion of the rye crop has been used for animal feed.

Rye is particularly susceptible to contamination with ergot, a toxic fungus that replaces the grain in the rye head during development, so that a long black ergot body protrudes from the mature head (*see* **Rye**). Ideally, the production of ergot in the crop is avoided, but there are techniques for the removal of intact ergot bodies prior to milling.

In addition to the manufacture of rye breads, rye-based crispbread is a major use of rye, generally with rye wholemeal or from flaked rye. Other baked products include Ryvita and pumpernickel. In human nutrition, the rye grain offers an unusually high level of pentosans. This source of soluble fiber offers advantages of giving a feeling of satisfaction, thus helping in slimming diets, as well as reducing the rate of rise in the blood sugar level after ingestion.

Triticale is a man-made crop that combines the genomes of wheat and rye (Table 1). It thus tends to be intermediate between rye and wheat in its grain composition and characteristics. The expectations for the grain have been that it would contribute the disease resistance and growth hardiness of rye to wheat, whilst also combining the baking quality of wheat with the unique flavor of rye bread. Triticale has thus been used for baking; nevertheless, its main use is for animal feed (*see* **Triticale**).

Sorghum and the Millets

The grains of sorghum and of various millet species (Table 1) constitute a major source of protein and energy for many people in Africa and Asia, where these grains are used as porridge, boiled in water after grinding. In such situations, these cereals offer the advantage for subsistence farming of tolerance to drought and suitability for dry tropical growth environments. Pearl millet is the most widely grown of the millet family, with an estimated growth area worldwide of ~30 Mha. Second in importance are common millet and finger millet (Table 1).

In addition to the use of sorghum in cooking, it is also dry-milled and fermented for various forms of beer. On the other hand, the main use of sorghum in developed countries is for animal feed, and to a lesser extent for industrial processing. There are various mutant forms of sorghum with distinct characteristics that include high lysine content, waxy starch, high sugar content, and even scented endosperm (*see* **Sorghum**: Breeding and Agronomy; Harvest, Storage, and Transport; Utilization). The grain of many sorghum varieties is pigmented, largely due to tannins located in the outer layers (testa) of the grain. The high-tannin varieties are also somewhat less nutritious, because the tannins interfere with protein digestibility. Some sorghum varieties have bitter flavors, which confer resistance to attack by birds.

Composition

Starch is the major component of the endosperm of the cereal grains (Table 7). It is the stored form of energy that is released on germination when amylase enzymes are produced to break the starch down to glucose units for the developing embryo, roots, and shoots. For feed and food, starch also provides the major source of energy, providing it in a "slow-release" form that is well suited to our digestive systems. Although cereal-grain proteins do not have the ideal combination of essential amino acids, being slightly deficient in lysine especially, they are generally ingested together with other sources of protein whose amino-acid composition complements that of the grains. The relatively low fat content of the cereal grains is a dietary advantage, especially when coupled with the levels of nonstarch polysaccharides, which act as important sources of fiber in the human diet.

The Supply Chain of Cereal Production and Processing

All cereal grains follow the sequence shown in Figure 9 in their production through to utilization. The initial stage involves the production of the seed for sowing. It is important for the farmer to have the most appropriate variety (genotype) that suits the expected

Table 7 Approximate composition of the major cereal grains, as percentages of dry weight of whole grain, except for rice

Component	*Wheat*	*Rice (milled)*	*Maize*	*Barley*	*Oats (groats)*	*Rye*
Starch	75–80	85–90	75–80	75–80	70–80	75–80
Protein	9–16	8–11	10–12	9–12	12–15	12–15
Fat	2–3	0.5–1.0	4–10	1–2	6–8	1–2
Crude fiber	2–3	0.2–0.6	2–3	5–6	1–2	2–3
Minerals	1–2	0.4–0.6	1–2	2–3	2–3	2–3

In addition, grain ("as is") would contain moisture at a level of 9–15%.

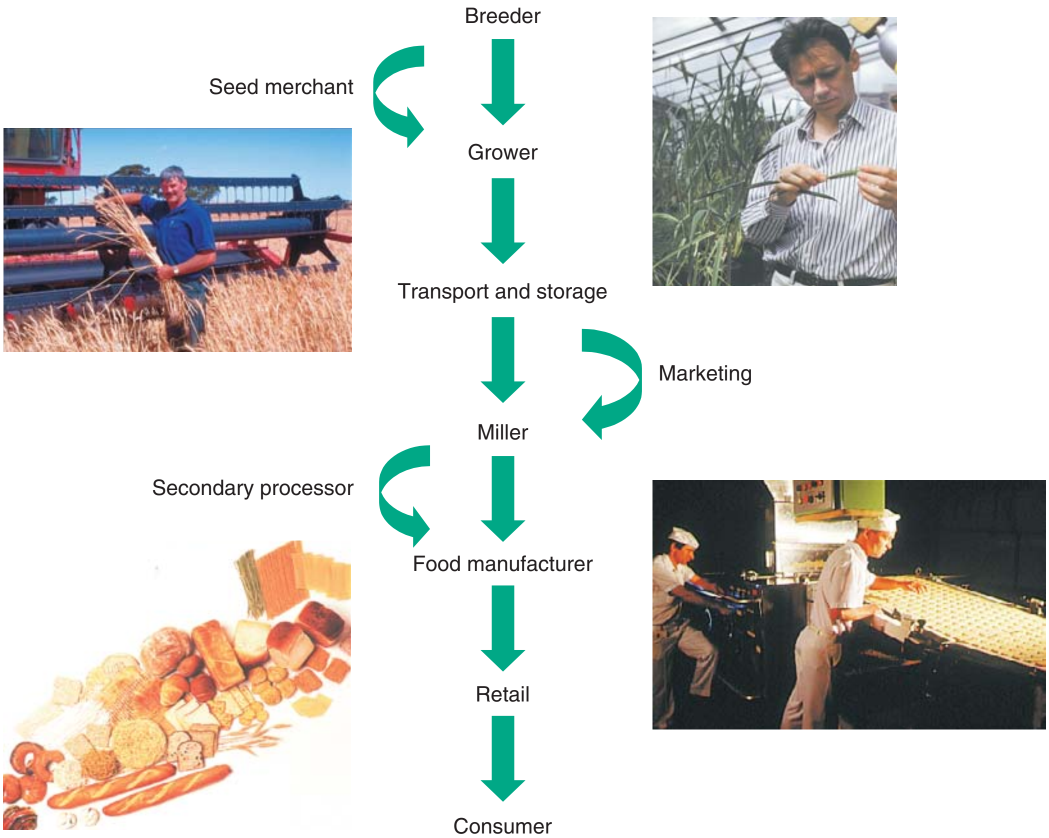

Figure 9 The grain supply chain extends from the breeding of a variety through to the food product reaching the consumer.

growth conditions, and that will produce grain with desired qualities for the planned use. Plant breeding has developed during the past century as the means of producing suitable genotypes, selecting them on the basis of the required attributes, after the use of cross-breeding to expand the genetic diversity available from which to make the selections.

Following the stages of breeding, selection, and registration (*see* **Variety Registration and Breeders' Rights**), there is the task of propagation and distribution of pure seed for sowing. Choice of the most appropriate variety is the first of many choices of farm management that must be made by the grower. Other management issues include soil preparation, fertilizer use at sowing and during growth, sowing rate, the possible use of irrigation and of herbicides and pesticides, and finally the harvest of the mature crop.

Even before harvest, the grower may have negotiated marketing of the crop, based on expectations of yield and quality attributes. Delivery arrangements might involve delivery of the harvested grain to a nearby storage facility ("elevator" or "silo"), or directly to a flour mill or feed mill (Figures 10 and 11). Further transport may involve delivery to the export terminal for loading into the hold of a ship (Figure 12). In many grain-producing regions, farmers

Figure 10 Grain being tipped from the farmer's truck for delivery at the country storage facility.

Figure 11 Grain storage facilities are generally situated beside rail connections to facilitate transport to mill or export terminals.

Figure 12 Loading grain into the hold of a ship for international trade.

store the harvested grain on their own properties, using the postharvest period to negotiate the prices and conditions of delivery. In any case, some grain is likely to be stored on-farm for seed use in the next season and for animal feed. In situations of subsistence farming, the family will be directly dependent on the stored grain for the coming year.

Depending on what type of grain has been produced, there is likely to be the need for further storage and transport prior to milling or processing plant, followed by delivery of the product to retail outlets. The final test of any product for sale is the consumer, who provides the "proof of the pudding," whatever form the "pudding" might take.

Cereal Grains and Our Health

For some individuals, cereal-based foods may cause dietary problems. One of the best characterized of these intolerances is celiac disease, a condition caused

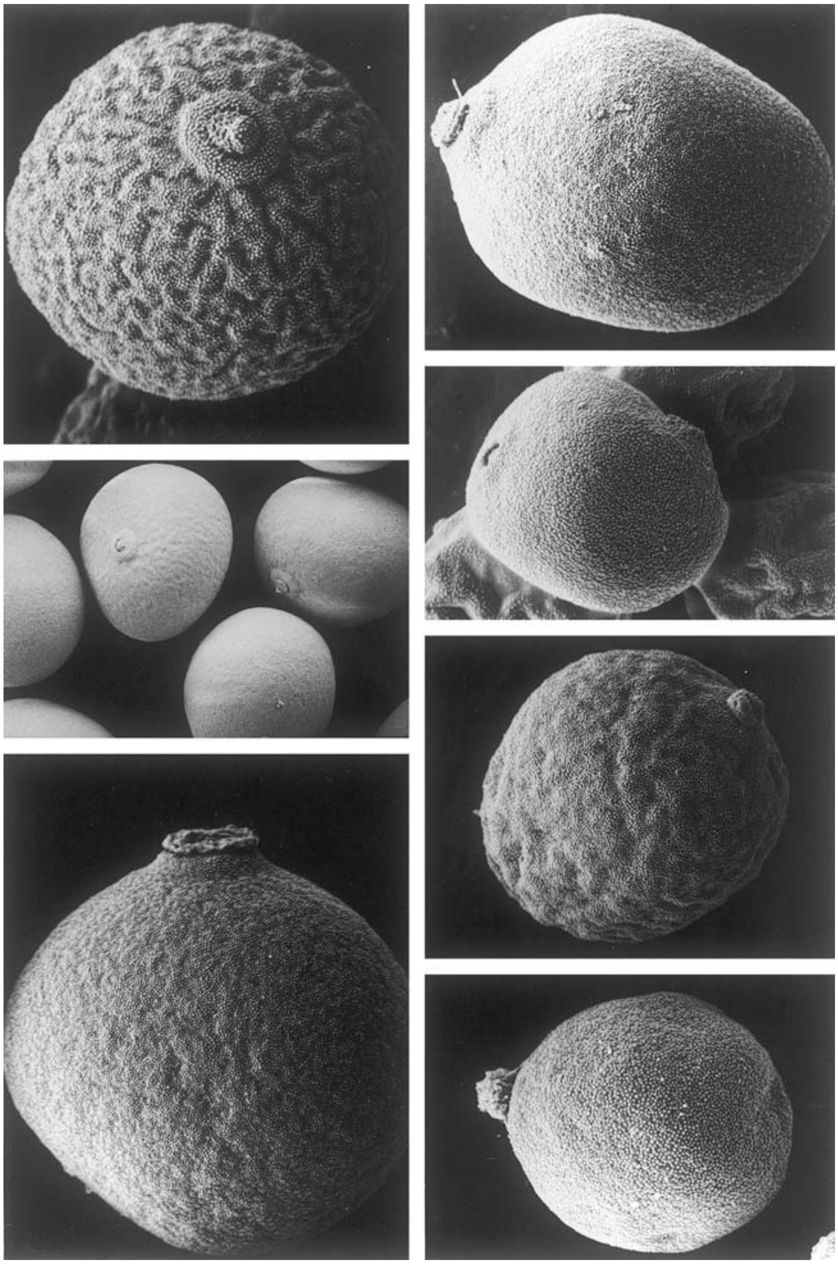

Figure 13 Pollen grains, revealed by scanning electron microscopy.

by the ingestion of wheat gluten protein, and of related grain proteins, namely, rye, triticale, barley, and sometimes oats. Despite its misleading name, buckwheat is not a grain that is toxic to celiacs (*see* **Celiac Disease**).

On the other hand, the cereal grains (milled or not) provide good sources of protein, fiber, and complex carbohydrates, earning for the cereal grains a major place in dietary guidelines. Additional health benefits may be provided by the inclusion of the outer layers of the cereal grains, in whole-grain foods. This is because these parts of the grain (Figure 2) provide an additional source of vitamins and minerals, and because they contribute increased amounts of fiber to the diet (*see* **Whole-Grain versus Refined Products**).

During their growth, the cereals also produce pollen that may cause allergy problems on inhalation. The pollen grains of the various cereal flowers have distinctive shapes (Figure 13). The germination of the pollen grain commences on exposure to moisture,

normally when it alights on the stylus of a flower of the same species, but the same reaction may occur if the pollen comes in contact with the mucosa of the respiratory tract. The proteins so released may cause swelling of the mucosa, resulting in rhinitis and asthma. The cultivated cereals may be the cause of this scenario, but it is more common for inhalant allergy to be caused by a wider range of plants species, not necessarily propagated for their grain.

Future Prospects

Despite the success of the cereal grains as the major food source for mankind, there are many stresses that reduce the yield and quality of the grain produced, necessitating continuing research effort to improve performance. These stresses include a range of pathogens and predators, as well as many abiotic factors (heat, cold, frost, drought, waterlogging, and heavy-metal toxicity). Traditional breeding has provided great improvements and it will continue to do so. These advances are being assisted by the identification and characterization of specific remedial genes. Some of these genetic opportunities lie in plants of species distantly related to the species of interest.

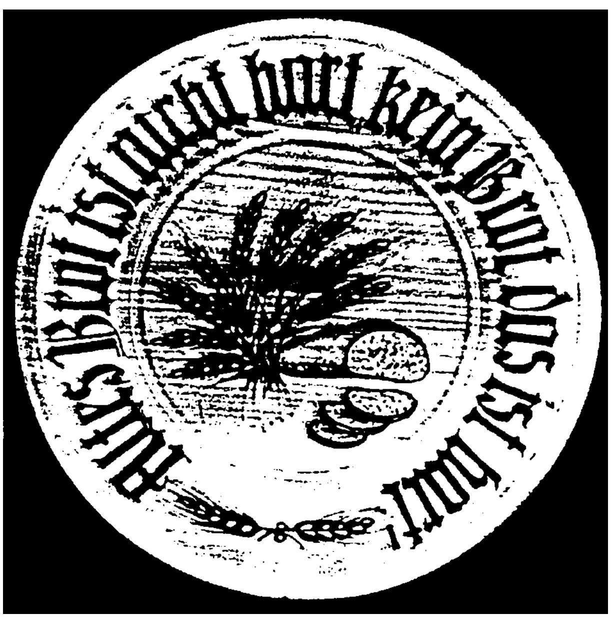

Figure 14 The inscription on this old plate portrays the ongoing problem of finding enough grain to provide food for everyone in the world. The words "Altes Brot ist nicht hart – kein Brot, das ist hart!" translate as "Old bread is not hard – no bread, that is hard." (Reproduced with permission from Ng PKW and Wrigley CW (eds.) (2002) *Wheat Quality Elucidation*. St. Paul, MN: American Association of Cereal Chemists, p. 24.)

Novel genetic technologies may now facilitate these cross-species transfers, thus augmenting conventional breeding, leading to new varieties that can better survive stresses, plus providing novel grain qualities. The composition and functional properties of the edible grains offer a wide diversity of possibilities for new and varied end uses. Given this genetic diversity, and the consequent access to the genes responsible, combined with the capabilities of novel methods of genetic manipulation, we have many possibilities for extending the compositional diversity of any grain to provide it with new functional properties.

There remains the overwhelming problem of how mankind can share the cereal-grain harvest more equally. This problem is epitomized in the inscription on the old plate in Figure 14; the translation reads: "Old bread is not hard – no bread, that is hard."

Breakfast Cereals

E F Caldwell, Arden Hills, MN, USA
R S Kadan, USDA, New Orleans, LA, USA

Introduction

The breakfast cereal industry, in its history of over 110 years, has emerged as an important segment of the food industry. Annual supermarket sales of all grain-based breakfast products in the USA were about \$11 billion (1.1×10^{10}) in 2002. Well over half of this (\$6.6 billion) came from sales of a billion kg (2.2 billion lb) of packaged ready-to-eat (RTE) breakfast cereals. This remarkable progress has been achieved through a combination of knowledge gained in human nutrition, creative formulation (including presweetening), innovative progress in cereal processing technology, and imaginative marketing. The chief driving force has been the continued market for new, convenient, nutritious, and fun foods, many of them with special appeal to children in a discriminating, affluent, and mobile society.

Any large grocery store in the USA, Canada, the UK, or Australia is likely to stock 150 or more different grain-based breakfast cereal products. In the UK, annual sales are about £1 billion (1×10^9). Penetration of these specific products into other European, Asian, and African countries is much lower, although consumers in Asian countries may well eat rice at breakfast as they do at other meals. Consumption of breakfast cereals as such increased significantly in continental Europe and in Japan during the 1990s, in both cases associated with growing indigenous manufacture and marketing. This has continued into the current century and is forecasted to continue.

Breakfast cereals have been defined as "processed grains for human consumption." The major grains used in their manufacture are corn, rice, wheat, oats, and barley. Breakfast cereal products can be divided into: (1) those that are RTE before or after adding milk and (optionally) sugar; (2) those that are ready-to-cook, also known as hot cereals (HCs); and (3) alternative breakfast products based primarily on cereal grains, such as cereal bars (some of which border on confectionery), toaster pastries, waffles and other frozen products, muffins, and bagels. This article deals primarily with RTE and HC products.

RTE cereals are frequently made from mixtures of one or several grain components with other ingredients; they require extensive processing, are usually fortified with vitamins and minerals, and are specially packaged to protect their flavor, texture, and nutrition during storage as well as display their contents in such a way as to visually appeal to and entice the consumer. They typically represent almost 90% of the combined volume of RTE and HC products. On the other hand, HC products are typically made from a single grain component by using relatively simple processing and packaging technologies. The difference between the RTE and HC products is reflected in the price at the consumer level. The usual single serving (28–35 g, or 1 oz) of RTE cereal costs consumers about \$0.20 (0.08–0.40) at retail in the USA, whereas a typical one-ounce serving of HC costs consumers about half of that (\$0.06–0.24, for bulk-packaged product to instant single-serving pouches, respectively).

While annual sales in the USA of the various grain-based alternative breakfast products had grown to substantially over \$3 billion (3.25×10^9) by 2002, the per capita annual consumption of RTE cereals had leveled off to under 5 kg (11 lb), and

that of HC products (at one time over 1 kg) had declined to less than 0.6 kg (1.3 lb). HC consumption would have been even lower were it not for the emergence and proliferation of so many instant portion-pack products. The latest per capita annual consumption figures in the UK were 5.9 kg (13 lb) and 0.6 kg (1.4 lb) for RTE and HC, respectively, with similar numbers in Canada, Australia, and New Zealand as contrasted with as low as 0.1 kg in other parts of the world.

Methods of Manufacture

RTE Cereals

RTE breakfast cereals are primarily grain formulations, suitable for human consumption without further cooking. Manufacturing technology varies according to type of cereal, whether flaked, puffed, shredded, granola, extruded, expanded, or baked. Representative samples are shown in Figure 1.

Flaked cereals Flaked RTE breakfast cereals can be divided into two groups: flakes rolled from whole grains or parts of the whole grains, and flakes made from more finely ground materials that are first extruded into pellets and then rolled into appropriate size flakes.

The whole grains (typically wheat or rice) or major components (such as grits from de-germed yellow maize or corn) are cooked with flavorings such as sugar, salt, and malt; they are then dried and tempered to a firm but slightly plastic state, flaked by passing between rolls, and toasted or dried to a final specified moisture content. Cooking of grits or whole grains for traditional flakes is usually done in batches. The moisture content of the cooked mass at the end of cooking is usually ~28%. The cooked material should not be mushy, soft, or sticky. After cooking, the mass of material is cooled, dried at ~120°C, and tempered (held) for several hours at a final equilibrated moisture content of 10–18%, depending upon the grains. The tempering process is important, not only to allow equilibration of moisture within the cooked grains or pellets, but also to allow sufficient starch recrystallization or retrogradation to provide a suitable texture for flaking (or for shredding, as discussed next).

Flaked RTE cereals are also made from extruded pellets rather than cooked grits or whole grains. A variety of floury or finely ground grain products such as whole wheat or oat flour can be mixed with sugar, salt, and malt syrup or other flavoring and coloring ingredients to form a dough. This is then extruded to form pellets about the same size as cooked grits or whole grains, the cooking having taken place in the extruder. Pellet moisture is in the range of 18–24%. Conditioning or tempering prior to flaking may or may not be required.

Whether consisting of cooked grits, cooked whole grains, or extruded pellets, the tempered material is then flaked. Tremendous pressures are necessary to flatten the prepared material into thin flakes, which traditionally are toasted by keeping them suspended

Figure 1 Some common RTE cereals. Clockwise from the top left, they are, respectively, flaked, puffed, shredded (bite-size), granola, extruded expanded, and baked products.

in hot air between 270°C and 330°C for ~90 s. Certain properties of the finished flakes can be modified by a heating or steaming step immediately before flaking (e.g., infrared heating immediately before flaking will increase the tendency of flakes to crinkle rather than remain flat), while other properties – such as blistering, color, crispness, tenderness, and flavor of the final product – are influenced by toasting conditions. The moisture content of the finished product is ~1–3%.

Puffed cereals The predominant grains used for making puffed cereals are wheat and rice. The milled rice that is used for puffing is either short- or medium-grain white rice. Such rice usually requires no pretreatment other than the hull and bran removal that occurs during milling or pearling. Wheat, on the other hand, is usually decorticated (bran removed), either by pretreatment with concentrated brine solution or by pearling. In the pearling operation, the grain is passed through a revolving cylinder inside which are mounted silicon carbide or carborundum stones.

Usually hard wheat, preferably durum, is used for puffing. A grain flour mixture can also be formed into desired shapes by an appropriate extrusion process and dried to a moisture content of 9–12% for subsequent gun puffing.

Puffing guns are vessels capable of holding very high temperature and high-pressure steam. The critical feature of any puffing gun vessel or barrel is a quick opening lid that seals the vessel. Operation of a simple single-shot gun consists of placing the grain in the vessel, closing the lid, and raising the pressure and temperature in the vessel to ~1380 kPa (200 psi). The quick-opening lid is then activated, causing rapid pressure drop, which in turn instantaneously causes moisture in the grain to "flash off" as steam, and the kernels of grain or preformed pellets to expand to as much as 16 times their original volume. Modern puffing guns can be multiple shot automatic, or can be continuous in operation. In the latter case, the grain kernels or preformed pellets are conveyed through a pressure vessel to which they are admitted and from which they are ejected via an orifice or mechanical device without loss of pressure inside the vessel.

Another group of RTE products is made by oven puffing. Specially prepared rice or corn grains or their mixtures are oven-heated to 290–340°C in order to puff them. Puffed rice cereal marketed in the USA is either oven-puffed (e.g., Rice Krispies, prepared from short-grain rice) or gun-puffed (e.g., Puffed Rice). Whether gun- or oven-puffed, the grains are then screened to remove any unpuffed kernels, loosened bran, fine dust, and broken kernels, and the product is heated to lower the final moisture to 1–3%. Processes such as sugar coating or the addition of vitamin enrichment can be carried out during this drying operation.

Shredded cereals Shredded wheat, one of the oldest mass-produced breakfast cereals, is still an important product. Soft white wheat is the primary grain used. Other classes of wheat, as well as other cereal grains such as rice, corn, or oats, or mixtures thereof, can also be used to make shredded products. The grains are cleaned, cooked in boiling water, partially dried, and tempered. The shredding operation consists of passing the tempered grain between two rolls. One roll is grooved and the other is smooth. Strong forces in the range of 7000 kPa (1000 psi) along the roll length are often required to maintain the rolls in tight contact. The tempered kernels are squeezed into the grooves of the roll and emerge as strands roughly 1 mm in diameter. These strands are accumulated in multiple layers below multiple pairs of rolls, and formed into biscuits or bite-sized pieces. A refinement of the shredding process is the use of a roll with added cross-grooves to provide lateral strands that can tie the shreds together in a coherent sheet. Alternatively, mixtures of ground cereal products with sugar, salt, malt, and flavoring can be cooked by extrusion, formed into pellets, tempered, and then shredded in the same way as cooked whole grain kernels.

The formed biscuits or pieces are oven dried and baked to desired color, texture, and moisture. The baking procedure is done in a specialized manner to impart fluffy texture, particularly for products containing rice or corn. Other minor ingredients – such as sweetening or other flavorings, nutrients, or antioxidants – can also be added prior to drying and baking.

Granola cereals The main grain used to make granola cereals is either regular or quick-cooking (thin-flaked) rolled oats. The cereal products are mixed with other desired ingredients such as nut pieces, coconut, corn syrup, brown sugar, honey, malt extract, dried milk, dried fruits, and/or vegetable oil. Liquid and dry ingredients are prepared separately, then mixed together and spread in a uniform layer on the band of a continuous oven, with baking temperatures in the range of 150–220°C. When the product is uniformly toasted to a light brown color and the moisture is reduced to ~3% after baking, the product is broken into small pieces and packaged.

Extruded expanded cereals Successful application of extrusion technology for producing RTE cereal products from grain flours or meal mixtures by formulating, continuous preconditioning, extrusion cooking, and forming has been an important achievement of the breakfast cereal processing industry. The extruders can be single screw, twin screw, low shear, high shear, and combinations of these or other features. Extrusion technology was developed to produce flaked, puffed, shredded, and expanded breakfast cereals. For extruded expanded cereals, cereal flour mixtures having ~25–30% moisture are preconditioned, cooked, and extruded. Perforations in the die and design of the cutoff knives at the end of the extruder, as well as temperature, pressure, dwell time, and shear in the extruder barrel, all influence the shape, size, and texture of the final product. The sudden change from high pressure and temperature to ambient conditions as the product exits the extruder imparts the necessary expansion, texture, and other characteristics. The extruded products may be coated with solutions of vitamins and minerals, and with sweetening and flavoring materials to enhance their sensory appeal (especially to children), and are then oven-dried to desired moisture levels.

Other RTE cereal types A breakfast cereal can be manufactured using essentially baking or cookie technology to form and cook the pieces. Another type is compressed-flake biscuits, formed from the compression of previously cooked and flaked grains, usually wheat flakes with added sugar, salt and malt, or other flavorings as described above. So-called muesli RTE cereals are mechanical mixtures of several ingredients. In Europe, the major ingredient is quick-cooking rolled oats mixed with sweetening and flavoring components but not otherwise processed. In the USA, a major component can also be processed and toasted flakes from various grains. Either kind is eaten with added milk and sugar.

Hot Cereals

HCs are products of a single grain or a simple mixture that require cooking or heating in water before consumption. The main such products are rolled oats and related oat products, farina and other wheat fractions, and corn grits.

After cleaning, oat kernels are de-hulled by an impact process. The resulting groats are steamed, primarily to deactivate lipolytic enzymes, then rolled, dried, and packaged. Quick-cooking rolled oats are made by steel cutting groats into four or five pieces before the steaming and flaking process. Instant oatmeal is made by subjecting groats to a special process that results in rapid cooking extra-thin flakes. Incorporation of 0.1–1.0% of an edible gum during processing helps to achieve this objective. Distribution of the gum and necessary salt without damaging the flakes is accomplished during portion-control packaging. Such instant products require only the addition of boiling water, stirring, and a short standing time to make the product ready for consumption. The industry has successfully incorporated dried fruits, nuts, and other flavorings to make instant oatmeal products more attractive to consumers.

Wheat farina is another important HC. In the USA, farina and enriched farina must meet respective legal standards of identity. Farina is basically wheat endosperm, preferably obtained from hard red spring or winter wheat, the granules of which stay intact during cooking at home. Farina is normally obtained by drawing off chunks of endosperm during milling of wheat into bread flour. In the UK it can also be called semolina, but in the USA that term is reserved for a similar product from durum wheat intended for macaroni and other pasta products. Farina is heated at ~60°C for 15 min before packaging, to enhance flavor and head off infestation. Quick and instant farina products are prepared by using disodium phosphate, enzymes, and other treatments including pre-cooking and drum drying. Wheat germ, bran, malted barley, cocoa, and other flavorings can be mixed into farina to enhance the consumer appeal.

Other important HC products include wheat products such as cracked wheat and bulgur, and corn grits. Grits and bulgur are generally used as cereal accompaniment to other meal menu components such as eggs, sausage, meat, and related preparations, whereas cracked wheat products are cooked for breakfast. Grits usage is mostly in southern parts of the USA, garnished with butter and salt rather than with sugar and milk as for traditional breakfast cereals. Grits are produced by dry milling of white de-germed corn and can be fortified with vitamins and minerals. Bulgur or parboiled wheat is one of the oldest cereal-based foods and has been consumed for centuries in Turkey, Syria, Jordan, Lebanon, and Egypt. To prepare it, common hard or soft wheat varieties are soaked in water and heated to ~90°C for 2–3 h. The cooked wheat is then cooled, dried, moistened, peeled (optional), re-dried, cleaned, and sized. Bulgur has good shelf life, because cooking destroys insects present in harvested crops and distributes nutrients uniformly throughout the kernel. It does not render the final product quick-cooking or "instant."

Significance in the Diet and Fortification

Breakfast cereals are one of the most highly fortified foods in both vitamins and minerals. One serving often can supply up to 25% of the daily values (DVs) of most vitamins and trace minerals as these are defined in the USA for labeling purposes. Some products supply 100% of all established DVs, making them as much nutritional supplements as breakfast foods. The cereal industry justifies these practices on the basis that they fulfill a genuine need to improve the overall nutritional needs of consumers. Past food consumption surveys showed that some of the US population had inadequate intakes of several vitamins and minerals, particularly vitamin A, folic acid, calcium, and iron, and possibly vitamin B_6, zinc, and magnesium.

In the US, the practice of fortification of cereal foods started in 1941, when the Food and Drug Administration (FDA) established a standard of identity for enriched flour to include the addition of thiamin, niacin, and iron. Riboflavin was subsequently included, and addition of calcium and vitamin D was optional. Such recommendations developed after extensive discussions by various committees of the American Medical Association, hearings sponsored by the FDA, and the Food and Nutrition Board. As a result, criteria for fortification of foods were developed:

1. the intake of nutrient is below the desirable level in the diet of a significant number of people;
2. the food used to supply the nutrient is likely to be consumed in quantities that will make a significant contribution to the diet of the population in need;
3. the addition of nutrient is not likely to create imbalance of essential nutrients;
4. the nutrient added is stable under proper conditions of storage;
5. the nutrient is physiologically available from the food; and
6. there is reasonable assurance against excessive intake to a level of toxicity.

Various studies have confirmed that fortification of BC foods is appropriate and has contributed significantly to improving overall nutrition. Fortification of flour and other grain-based foods with folic acid became a requirement in the USA in 1998 because of evidence that it may help prevent neural tube defects.

Many nutritionists consider eating breakfast regularly as one of the important health habits associated with subsequent favorable health status and reduced mortality. People who had breakfast were found to do significantly more work in the morning than those who did not. Children and the elderly (above 65 years old) are the largest consumers of breakfast cereals. Half or more of the school-age children in the USA prepare their own breakfast, because most of their parents work outside the homes. These groups are more likely to skip breakfast. Studies have confirmed that consumers of RTE breakfast cereals are likely to skip fewer breakfasts and that they obtain higher levels of vitamins and minerals than others. Some products contain up to 5 g of dietary fiber per serving. Some high-fiber products can even provide 10 g or more of fiber and thus help consumers to improve their dietary fiber intake to meet recommendations of 25–30 g daily dietary fiber intake. Oat-based breakfast cereals containing sufficient β-glucan soluble fiber to provide 3 g or more of that substance daily, or other products containing sufficient psyllium to provide 7 g of soluble fiber from that source daily, have been shown to decrease blood cholesterol by a small but significant amount, and in the USA may carry label health claims to that effect. Recent studies have shown that diets rich in whole-grain foods (such as breakfast cereals with whole grains as a major constituent) and other plant foods that are low in total fat, saturated fat, and cholesterol may reduce the risk of heart disease and cancer.

Most breakfast cereals are not high in protein, and the protein in some of them, such as gun-puffed or flaked products, may have little or no biological value due to excessive Maillard browning. RTE cereals as marketed may also be high in sugar and/or salt (sodium) and may contain added saturated fat, but with milk and fruit still make an inexpensive, nutritious, and easy-to-prepare breakfast.

Packaging, Storage, and Spoilage

The industry over the years has developed efficient processing, packaging, storage, and shipping technologies to supply consumers with cereal foods that routinely have 6 months or longer shelf life. It is indeed quite a feat to have such an array of vitamins and minerals, which often interact with each other, in a highly processed food and yet end up with a wholesome product with a desirable flavor and texture. Novel techniques have been developed for vitamin preservation and for the incorporation of antioxidants such as BHT directly or via the packaging material. The package not only protects the product against moisture, oxygen, and insects during shipping and storage, but also provides attractive consumer appeal at the point of purchase. The industry has accomplished this by following “good manufacturing practices” and other quality control measures, and by instituting hazard analysis and critical control point (HACCP) systems for food safety purposes.

Computer control of processing and attention to environmental issues also characterize most breakfast cereal manufacturing operations, and certainly the newer ones.

Future Developments

The Nutritional Labeling and Education Act of 1990 and subsequent amendments in the USA undoubtedly contributed to re-evaluation of product development, marketing, and advertising strategies by the breakfast cereal industry as a result of stricter control of nutrient claims, ingredient listing, and other label data. Among other moves, the industry has developed new products made from whole grains that are also low in fat, sugar, and salt (sodium), with encouragement provided by FDA approval of a health claim for products containing one or more whole grains as a majority constituent. Other product developments or modifications are likely to be influenced by such regulatory developments as well as by advances in technology or nutritional knowledge.

Chemistry of Nonstarch Polysaccharides

G B Fincher, University of Adelaide, Glen Osmond, SA, Australia
B A Stone, La Trobe University, Bundoora, VIC, Australia

Introduction

The nonstarch polysaccharides of cereal grains include cellulose, (1→3, 1→4)-β-D-glucans, heteroxylans (arabino-xylans), glucomannans, xyloglucans, pectic polysaccharides, callose, fructans, and arabinogalactan-proteins. With the exception of the fructans and the arabinogalactan-proteins, all are key components of the walls of cells in the various tissues that comprise the grain (Figure 1a) (*see* **Grain, Morphology of Internal Structure. Grain and Plants, Morphology**). The cells of the various tissues have diverse functions during grain development, dormancy, and after germination. The pericarp and

seedcoat tissues are concerned with the protection of the seed during development and dormancy. However, at grain maturity, these tissues are dead and consist almost entirely of cell walls. The nucellar tissue between the seedcoat and the aleurone surface is involved in transfer of nutrients to the developing grain but has collapsed at maturity to leave cell-wall remnants. Cells of the starchy endosperm are dead, but

[b] Some genotypes had very low glucomannan content.

are packed with starch and storage protein and are usually thin-walled. In contrast, the thick-walled, nucleated, aleurone cells are alive at grain maturity, and are packed with protein bodies and lipid droplets. The living embryonic tissues of the germ are differentiated into the functional cell types found in shoot and root. At the interface of the starchy endosperm lies the scutellum, which delivers nutrients to the developing endosperm and during germination transfers digestion products of the endosperm reserves to the developing embryo.

The cell-wall composition and organization of the cell types found in the tissues of the grain reflect these different functions and in turn determine their nutritional impact and the behavior of various grain parts in technical operations during grain utilization.

Together the nonstarch polysaccharides usually constitute less than 10% by weight of the grain (Table 1), but can nevertheless be key determinants of grain quality. Although the precise physical relationships between individual nonstarch polysaccharides and other wall components have not been described, it is generally considered that in the wall, microfibrils of cellulose are embedded in a matrix phase of noncellulosic polysaccharides and protein (Figure 2). Wall integrity is maintained predominantly through extensive noncovalent interactions, especially hydrogen bonding, between the matrix phase and microfibrillar constituents. In the walls of some grain tissues, covalent associations between heteroxylans, lignin, and proteins are present. The extent of covalent associations between components also varies with the wall type and genotype. The relative ease of extraction of noncellulosic polysaccharides from the different wall types in cereal grains is strongly influenced by these interactions.

Noncellulosic polysaccharides, especially heteroxylans and (1→3, 1→4)-β-D-glucans, constitute a relatively high proportion of the walls of the aleurone and starchy endosperm, and probably also of the scutellum. Cellulose contents are correspondingly lower (Table 2). The generally low cellulose content of these walls, together with the fact that they contain no lignin, might be related to a limited requirement for structural rigidity of walls in central regions of the grain, and to a requirement to rapidly depolymerize wall components following germination of the grain. In walls of cells in the multiple tissue layers of the maternally derived, pericarp–seedcoat, which provide a protective coat for the embryo and endosperm and which are not mobilized during germination, cellulose, and lignin contents are much higher and the concentrations of noncellulosic polysaccharides are correspondingly lower.

In this article, the chemistry and physico-chemical properties of nonstarch polysaccharides from cereal grains, which are important in human and animal nutrition and which have an impact in grain utilization and in cereal technology, will be described.

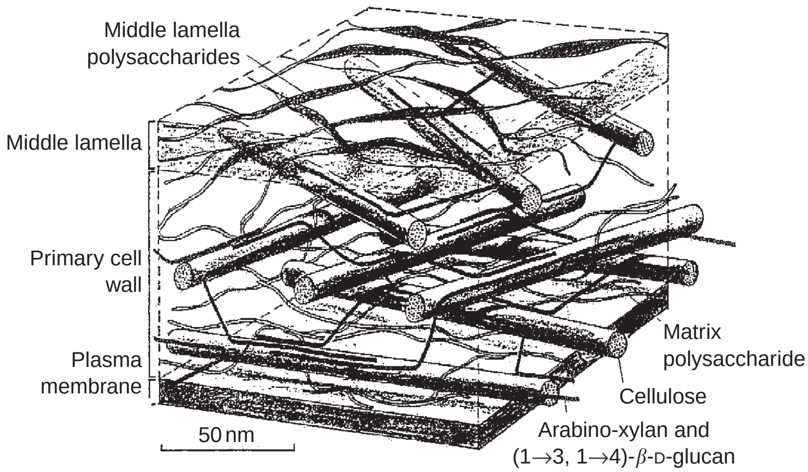

Figure 2 Organization of polymeric components in cell walls. A simplified schematic representation of the spatial arrangement of polymers in a primary wall, for example, from a starchy endosperm cell. Note the cellulosic microfibrils are embedded in a network of noncellulosic polysaccharides (arabinoxylans and (1→3, 1→4)-β-D-glucan) and protein (not shown). The noncellulosic polysaccharides can form associations with surfaces of several microfibrils and provide cohesive interactions. In some cells, e.g., those of the pericarp–seedcoat, a secondary wall is deposited between the primary wall and the plasma membrane and the water in the matrix of both the primary and secondary walls is replaced by lignin, a phenylpropanoid polymer that overlies and encrusts the cellulose microfibrils and noncellulosic polysaccharides and may be covalently bonded to the latter. (Reproduced with permission from McCann MC and Roberts K (1991) Architecture of the primary cell wall. In: Lloyd CW (ed.) *The Cytoskeletal Basis of Plant Growth and Form*, pp. 109–129. London: Academic Press.)

Cellulose

Cellulose is a component of all cell walls in cereal grains. However, its concentration varies widely. Cellulose is usually a minor constituent of the primary walls of starchy endosperm and aleurone cells of cereal grains, but its content is much higher in secondary walls of the pericarp and seedcoat cells (Table 1). It is a linear homopolymer composed of β-D-glucopyranosyl residues, all of which are (1→4)-linked (Figure 3a). Individual molecules have a degree of polymerization of up to 6000 in primary walls and 14 000 in secondary walls. The molecular chains have an extended, ribbon-like conformation that allows parallel packing of chains into three-dimensional, fibrillar aggregates stabilized by extensive intermolecular hydrogen bonding and van der Waals interactions (Figure 3b). These aggregates, termed microfibrils, are easily visible under the electron microscope, and may reach diameters

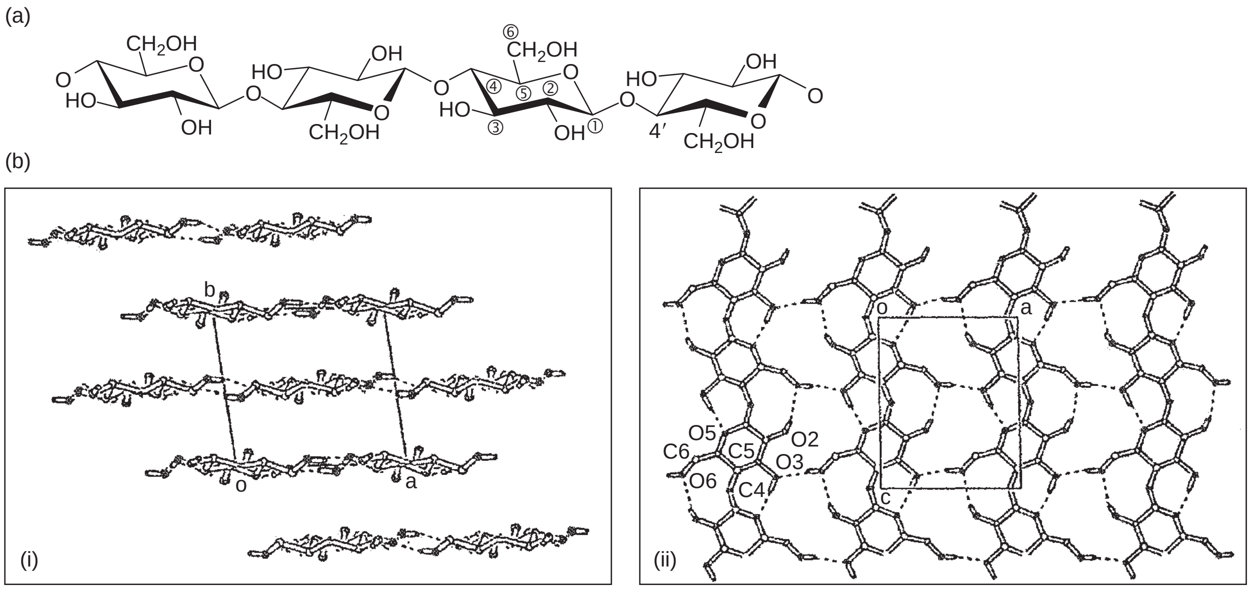

Figure 3 Cellulose structure. (a) Portion of a cellulose molecule. (b) Crystal structure of cellulose I: (i) projection down the fiber axis *c* showing the layers (sheets) of cellulose chains hydrogen-bonded in the *ac* plane but lacking intersheet bonding. The intersheet bonding involves van der Waals interactions between the hydrophobic faces of the glucose units. (ii) View of a layer approximately perpendicular to the *ac* plane showing the two intra-molecular hydrogen bonds in the direction of the fiber axis *c* and the inter-chain hydrogen bonds. (Reproduced with permission from Kroon-Batenburg LMJ and Kroon J *Carbohydrates in Europe* No. 12, 15–19.)

of 3 nm in primary walls and 5–10 nm in secondary walls. Within microfibrils, individual cellulose molecules are mostly packed into parallel, highly ordered, crystalline arrays, although there are usually regions where molecular alignment is less ordered. In particular, the surface molecules may have a different conformational and hydrogen-bonding arrangement compared with molecules within the more crystalline interior.

Cellulose microfibrils may also associate with water and matrix polysaccharides such as the (1→3, 1→4)-β-D-glucans, heteroxylans (arabino-xylans), and glucomannans.

Cellulose is insoluble in water but swells in concentrated sodium hydroxide solutions and may be brought into solution by powerful hydrogen-bond-breaking reagents such as N-methylmorpholino-N-oxide. Thermal and shear treatments, followed by alkaline peroxidation and shearing to remove lignin, have been used to convert cellulose-rich maize bran (Table 1) to a cellulosic gel for use as a dietary fiber supplement.

(1→3, 1→4)-β-D-Glucans

(1→3, 1→4)-β-D-glucans, also referred to as mixed-linkage or cereal β-glucans, occur almost exclusively in members of the monocotyledon family Poaceae, to which the cereals and grasses belong, and in related families of the order Poales *(sensu stricto)*. They are important constituents of the walls of the starchy endosperm and aleurone cells of most cereal grains, where they can account for up to 70% by weight of the walls (Table 1). The concentration of (1→3, 1→4)-β-D-glucans in cereal grains depends on the genotype, the position of the grain on the spike and environmental factors such as planting location, climatic conditions during development, and soil nitrogen. Barley, oat, and rye grains are rich sources of (1→3, 1→4)-β-D-glucans, whereas wheat, rice, and maize have lower concentrations of the polysaccharide (Table 2). The (1→3, 1→4)-β-D-glucans are relatively minor components of walls in vegetative tissues of cereals and grasses. A structurally related (1→3, 1→4)-β-D-glucan, lichenin, is found in the walls of the fungal component of the lichen, Iceland moss (*Cetraria islandica*).

Structure

(1→3, 1→4)-β-D-glucans are linear, unbranched polysaccharides in which β-D-glucopyranosyl monomers are polymerized through both (1→4)- and (1→3)-linkages (Figure 4a). The ratio of (1→4)- to (1→3)-linkages is generally fairly constant and in the range 2.2–2.6 : 1, although in the (1→3, 1→4)-β-D-glucan from sorghum endosperm, the ratio is 1.15 : 1. The two types of linkages are not arranged in regular, repeating sequences. Single (1→3)-linkages

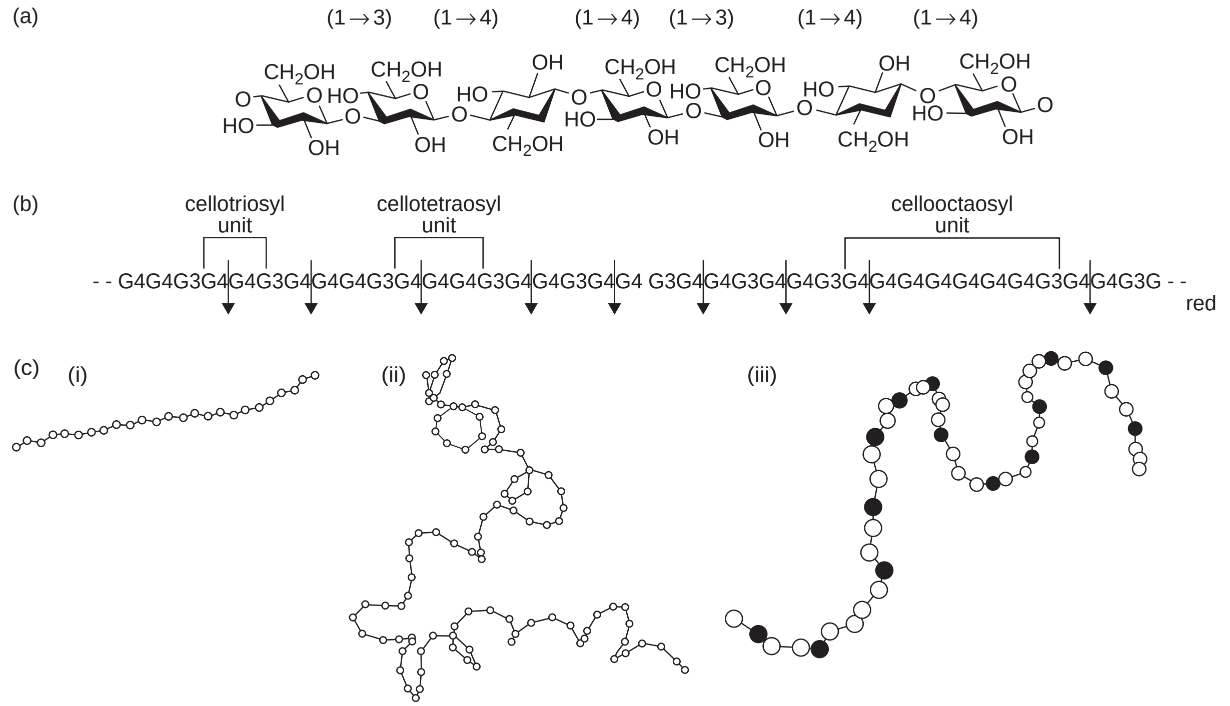

Figure 4 (a) Portion of a (1→3, 1→4)-β-D-glucan molecule. (b) Distribution of linkages in a (1→3, 1→4)-β-D-glucan. (G, β-glucosyl unit; 3, (1→3)-linkage, 4 (1→4)-linkage; red, reducing end, arrows, site of hydrolysis by (1→3, 1→4)-β-D-glucan endohydrolase [EC 3.2.1.73]. (c) Perspective drawings of computer-generated, instantaneous conformations of β-glucans: (i) (1→4)-β-D-glucan (cellulose), (ii) (1→3)-β-D-glucan (callose), (iii) (1→3, 1→4)-β-D-glucan (○), (1→4)-linked residues (●), (1→3)-linked residue. are separated by two or more (1→4)-linkages. Regions of two or three adjacent (1→4)-linkages predominate, but again there is no regularity in the arrangement of these units. The linkage sequence does not depend on preceding linkages further away than two glucose units and follows a second order Markov chain distribution. Moreover, up to 10% of the chain may consist of longer stretches of 5–20 adjacent (1→4)-linkages. Thus, cereal (1→3, 1→4)-β-D-glucans may be considered as (1→3)-β-linked copolymers of cellotriosyl ($G4G4G_{Red}$), cellotetraosyl ($G4G4G4G_{Red}$) units, and longer (1→4)-β-D-oligoglucosyl units (Figure 4b). The ratio of tri- to tetrasaccharide units varies between cereal species, as follows: wheat (3.0–4.5 : 1), barley (2.9–3.4 : 1), rye (2.7 : 1), and oats (1.8–2.3 : 1). The ratios vary according to the temperature and conditions of extraction.

Molecular Size

The average molecular masses reported for cereal (1→3, 1→4)-β-D-glucans range from 48 000 (degree of polymerization, DP, ~300) to 3 000 000 (DP ~1850), depending on the cereal species, cell-wall type, extraction procedure, and the method used for molecular mass determination. They are invariably polydisperse with respect to molecular mass and this is illustrated by a weight average to number average molecular mass ratio (M_w/M_n) of 1.18 for barley (1→3, 1→4)-β-D-glucan. Certain barley (1→3, 1→4)-β-D-glucans are covalently associated with small amounts of protein and have estimated molecular masses of up to 40 000 000.

Solubility

The extractability of (1→3, 1→4)-β-D-glucans from walls of cereal grains is a function of their degree of self-association and their association with other wall polysaccharides and proteins. In particular, extractability depends on the molecular mass and linkage distribution in the (1→3, 1→4)-β-D-glucan chains. Extensive association with other polymers and very high molecular masses will render the (1→3, 1→4)-β-D-glucans more difficult to extract from the grain.

A portion of the (1→3, 1→4)-β-D-glucan from barley, oat, and rye flours is extracted by water at pH 7.0 and 40°C. These flours consist predominantly of aggregates of starchy endosperm cells. Further fractions can be solubilized at higher temperatures. The proportion of total (1→3, 1→4)-β-D-glucan that is

water-soluble at 40°C varies within and between species. For example, waxy (high amylose) barleys have a higher proportion of water-soluble (1→3, 1→4)-*β*-D-glucan than normal barleys. (1→3, 1→4)-*β*-D-Glucans extracted from barley at 40°C have a slightly lower tri- or tetrasaccharide ratio (1.7 : 1) than those extracted at 65°C (2.0 : 1). Complete extraction of cereal (1→3, 1→4)-*β*-D-glucans from grain requires the use of alkaline extractants such as 4 M NaOH or aqueous $Ba(OH)_2$, containing $NaBH_4$ to prevent alkali-induced degradation from the reducing terminus. Alkali-extracted barley (1→3, 1→4)-*β*-D-glucan fractions have higher molecular masses, higher ratios of (1→4) : (1→3) linkages, more contiguously linked (1→4)-linked segments and higher tri- : tetrasaccharide ratios than their water-extractable counterparts. Other extractants, such as dimethylsulphoxide, hot perchloric acid, trichloroacetic acid, N-methylmorpholino-N-oxide, and dimethylacetamide-LiCl, have also been used to solubilize (1→3, 1→4)-*β*-D-glucans, but all are liable to cause some depolymerization or degradation of the polymer. Once extracted with hot water or alkali, the (1→3, 1→4)-*β*-D-glucans are soluble at neutral pH and room temperature. However, upon cooling, the (1→3, 1→4)-*β*-D-glucans slowly aggregate and precipitate.

Conformation in Solution

In aqueous media (1→3, 1→4)-*β*-D-glucans adopt a partially extended, somewhat rigid, reptate (snake-like) chain conformation (Figure 4c) with a cross-sectional diameter of 0.45 nm and a length : width (axial) ratio of ~100.

Solid-State Conformation

X-ray fiber diagrams of the water-soluble barley (1→3, 1→4)-*β*-D-glucan can be interpreted as a (1→3)-linked cellotriosyl polymer with a threefold screw axis and a fiber repeat of 4.2 nm. The shape of the chain is reminiscent of cellulose in the cellotriosyl and longer cellosaccharide units, but the (1→3)-linkages provide some helical character.

Viscosity of Solutions of (1→3, 1→4)-*β*-D-Glucans

The intrinsic viscosities of (1→3, 1→4)-*β*-D-glucan solutions are dependent on the cereal species from which the polysaccharide is extracted and on the solvent used. Intrinsic viscosity values for barley (1→3, 1→4)-*β*-D-glucans in water range from 4.6–6.9 dl g^{-1} and from 2.0–9.6 dl g^{-1} for oat (1→3, 1→4)-*β*-D-glucans. The extractability, solubility, and viscosity characteristics of cereal (1→3, 1→4)-*β*-D-glucans can be understood by reference to their fine structures. Long runs of adjacent (1→4)-*β*-D-glucosyl units in the (1→3, 1→4)-*β*-D-glucan chain will form extended ribbon-like cellulosic stretches, but the insertion of a (1→3)-linked glucosyl unit between them causes a "kink" in the molecule (Figure 3c). Chain flexibility arises principally from the isolated (1→3)-*β*-linkages. Because the (1→3)-linked *β*-glucosyl units do not occur regularly along the chain, the polysaccharides are not able to align over extended regions and hence remain "dispersed" and soluble in aqueous media. The overall extended polysaccharide conformation is due to the predominance of (1→4)-linkages and results in the occupancy of a high volume of solvent (high hydrodynamic volume). This results in aqueous solutions of high viscosity.

The viscosity of solutions of cereal (1→3, 1→4)-*β*-D-glucans depends strongly on concentration. At concentrations of oat (1→3, 1→4)-*β*-D-glucan where the total volume occupied by the chains is, in aggregate, less than the total volume of the solution, there is contact between individual chains, but the viscosity of the solution is independent of shear rate. At higher concentrations, there is interpenetration of the chains in response to increasing space occupancy. The viscosities of such aqueous solutions are reduced with increasing shear rate, a phenomenon known as "shear thinning." These different concentration-dependent rheological properties of (1→3, 1→4)-*β*-D-glucan solutions may be of significance in their physiological responses as food ingredients and in their use in food formulations.

Gelation

(1→3, 1→4)-*β*-D-glucan solutions at concentrations of 5% (w/v) or more form elastic gel networks. The gels are thermoreversible, exhibit broad melting transitions and show syneresis. Their melting temperatures depend on the source of (1→3, 1→4)-*β*-D-glucan, as follows: lichenin, 73°C; barley, 65°C, and oats, 62°C. These values are again related to tri- : tetrasaccharide ratios, which in these examples are 22 : 1, 3 : 1, and 2 : 1, respectively. In the gel state, the (1→3, 1→4)-*β*-D-glucan chains interact to form three-dimensional networks. Association between chains at junction zones, through pairs of consecutive cellotriosyl units, is proposed. This accounts for the higher melting temperature of lichenin gels, where cellotriosyl units make up most of the molecule. In the cereal (1→3, 1→4)-*β*-D-glucans, consecutive cellotriosyl units are less frequent, although the longer runs of adjacent (1→4)-*β*-D-glucosyl units, not present in lichenin, may also participate in junction zone formation.

The induction time for gelation depends on mobility and diffusivity. It increases with the molecular

mass of (1→3, 1→4)-β-D-glucan and decreases as the concentration increases. Gelation is repressed at high and low temperatures, where molecular motion is high and low, respectively. Gelation may be induced by homogenization, centrifugation, and by freezing and thawing.

Structure–Function Relationships in Cereal Processing and Nutrition

The viscosity-generating properties of soluble cereal (1→3, 1→4)-β-D-glucans are critical determinants in many aspects of cereal processing. For example, incompletely degraded (1→3, 1→4)-β-D-glucans from malted barley and cereal adjuncts can contribute to wort and beer viscosity and are associated with problems in wort separation and beer filtration. In other applications, (1→3, 1→4)-β-D-glucans can be cast as biodegradable films, have foam- and emulsion-stabilizing ability and, when used as a flour supplement, increase water absorption in doughs. Soluble cereal (1→3, 1→4)-β-D-glucans have "antinutritive" effects in monogastric animals such as pigs and poultry. The "antinutritive" effects have been attributed to the increased viscosity of gut contents, which slows both the diffusion of digestive enzymes and the absorption of degradative products of enzyme action. This, in turn, leads to slower growth rates. Moreover, in dietary formulations for poultry, high (1→3, 1→4)-β-D-glucan concentrations are associated with "sticky" feces, which are indicative of the poor digestibility of the (1→3, 1→4)-β-D-glucans and which may present major handling and hygiene problems for producers.

Cereal (1→3, 1→4)-β-D-glucans are important components of dietary fiber in human and animal diets. Humans and monogastric animals produce no enzymes that degrade (1→3, 1→4)-β-D-glucans, although there are indications that some depolymerization occurs in the stomach and small intestine, presumably due to the activity of commensal microorganisms. By comparison, the soluble (1→3, 1→4)-β-D-glucans and other nonstarch polysaccharides are readily fermented by colonic microorganisms and make a small contribution to digestible energy.

In contrast to their "antinutritive" effects in monogastric animals, oat and barley (1→3, 1→4)-β-D-glucans at high concentrations in human foods have beneficial effects, especially for noninsulin-dependent diabetics, by flattening glucose and insulin responses that follow a meal. High concentrations of (1→3, 1→4)-β-D-glucans (20% w/v) in food have also been implicated in the reduction of serum cholesterol concentrations, by lowering the uptake of dietary cholesterol or resorption of bile acids from the intestine.

Immuno-Modulatory Effects

(1→3, 1→4)-β-D-Glucans, in common with a number of other polysaccharides, in particular (1→3)-β-D-glucans, modify immunological responses in humans by a process that is mediated through binding to receptors on cells of the reticulo-endothelial system (leucocytes and macrophages). In addition, they may have the capacity to activate the proteins of the human complement pathway, a system that is invoked as a first line of defense before circulating antibodies are produced.

Analysis and Detection

Specific reagents for the analysis and detection of cereal (1→3, 1→4)-β-D-glucans include enzymes, fluorochromes, and monoclonal antibodies. The (1→3, 1→4)-β-D-glucan endohydrolase (EC 3.2.1.73) from *Bacillus subtilis* has been adopted for the specific quantitation of (1→3, 1→4)-β-D-glucan in grain or grain extracts. This enzyme cleaves only (1→4)-linkages that adjoin (1→3)-substituted glucosyl units in the glucan chain and therefore liberates a series of oligoglucosides with (1→3)-linked reducing units (Figure 3b). These may be quantified by β-glucosidase cleavage and measurement of the released glucose with the glucose oxidase-peroxidase reagent, by separation and quantitation by high-performance liquid chromatography (HPLC), or by matrix-assisted laser desorption ionization mass spectrometry (MALDI-TOF-MS). The latter procedures allow an assessment of the profile of oligosaccharides making up the primary structure of the (1→3, 1→4)-β-D-glucan and, in particular, the tri- : tetrasaccharide ratio.

β-D-Glucans, including the (1→4)-β-D-glucan, cellulose, the (1→3)-β-D-glucan, callose, and cereal (1→3, 1→4)-β-D-glucans, form complexes with the diphenyldiazo dye, Congo red, and members of the Calcofluor family of diaminostilbene sulphonates. These reagents complex poorly with heteroxylans and arabinogalactan-proteins. Irradiation of the complexes induces a brilliant red fluorescence in the case of Congo red (emission λ_{max} 590 nm, green excitation 470 nm) and a bright blue fluorescence with Calcofluor (emission λ_{max} 420, 442 nm; blue excitation 350 nm). The fluorochromes complex with and precipitate soluble β-glucans. Although complexing with the fluorochromes is not specific for (1→3, 1→4)-β-D-glucans, it is nevertheless useful in quantifying soluble (1→3, 1→4)-β-D-glucans with molecular weights of greater than 10 kDa in grain extracts and in products such as wort, where cellulose will not be present.

The fluorochromes and the (1→3, 1→4)-β-D-glucan-specific monoclonal antibody can be used to

locate (1→3, 1→4)-*β*-D-glucans in tissue sections in histological studies. Although near-infrared reflectance (NIR) spectra of polysaccharides are complex, making their direct interpretation difficult, principal component analysis of the spectra of different polysaccharides enables characteristic NIR wavelengths to be determined. NIR spectroscopy has been applied to the determination of (1→3, 1→4)-*β*-D-glucans in ground barley grain and this method forms the basis of rapid, routine (1→3, 1→4)-*β*-D-glucan estimation.

Genetics

(1→3, 1→4)-*β*-D-glucan concentrations in grain are influenced by both genotype and environment. Quantitative trait locus (QTL) mapping has enabled regions of the barley genome that control (1→3, 1→4)-*β*-D-glucan concentrations to be identified and placed on high-density genetic maps. Furthermore, the conservation of gene order (synteny) across cereal genomes means that regions controlling (1→3, 1→4)-*β*-D-glucan concentrations in cereals other than barley can often be deduced from the genetic positions of barley QTLs. This is of particular relevance when wheat, rice, or oats are to be used for human or animal nutrition.

The multigenic control of (1→3, 1→4)-*β*-D-glucan content in ungerminated barley grain is reflected in the mapping of QTLs to both chromosomes 1H and 2H. Although genes that contribute to (1→3, 1→4)-*β*-D-glucan content in ungerminated barley grain have not yet been identified, it is likely that at least some will encode (1→3, 1→4)-*β*-D-glucan synthases. Malt (1→3, 1→4)-*β*-D-glucan concentrations are determined not only by genetic factors that control their synthesis in the developing grain, but also by the speed and level of synthesis of degradative enzymes in the germinated grain. Thus, QTLs for (1→3, 1→4)-*β*-D-glucan content in malt extracts are found on barley chromosomes 1H, 3H, 4H, 5H, and 7H. Some of these QTLs may be related to concentrations of the various (1→3, 1→4)-*β*-D-glucan exo- and endohydrolases that degrade the polysaccharides in germinated grain and to factors that control grain germination more generally.

Heteroxylans

The cereal heteroxylans, or pentosans, are of two main types: the arabino-xylans and glucuronoarabinoxylans. They are characteristically abundant in walls of vegetative tissues of cereals and grasses. The arabino-xylans are the major noncellulosic polysaccharides in walls of the starchy endosperm cells and of the aleurone layer of cereal grains, whereas the glucuronoarabinoxylans are characteristically found in walls of the pericarp–seedcoat tissues (Table 1). Within a cereal species, heteroxylan concentration is influenced by both genotypic and environmental factors.

Structure

Cereal heteroxylans have a (1→4)-*β*-D-xylan backbone that has the same shape as the (1→4)-*β*-D-glucan, cellulose (Figure 3a). The *β*-xylopyranosyl (Xyl*p*) units of the xylan backbone are modified by side-chain branching (substitution) (Figure 5). The major side-chains comprise single *α*-L-arabinofuranosyl (Ara*f*) units, situated predominantly at C(O)3, but in certain species also at C(O)2 of the Xyl*p* units. In some cases, Ara*f* substitutions occur at both C(O)3 and C(O)2. The frequency of Ara*f* substitution depends on the cereal species and wall type and is reflected in a very wide range of Xyl*p* : Ara*f* ratios (0.89–13 : 1). The Xyl*p* units of cereal arabino-xylans may be acetylated. In sorghum heteroxylans, acetyl groups are present on both the C(O)2 and C(O)3 of xylopyranosyl residues. Heteroxylans from cell walls in vegetative tissues, especially lignified walls such as those from parenchyma, sclerenchyma fibers and the pericarp–seedcoat tissues that are found in cereal brans, have low degrees of Ara*f* substitution and therefore high Xyl*p* : Ara*f* ratios. On the other hand, heteroxylans from the aleurone layer and starchy endosperm have relatively low Xyl*p* : Ara*f* ratios.

The distribution of Ara*f* units along the xylan chain is not regular. In one wheat arabino-xylan fraction, three major types of substitution patterns have been identified in different regions of the xylan backbone

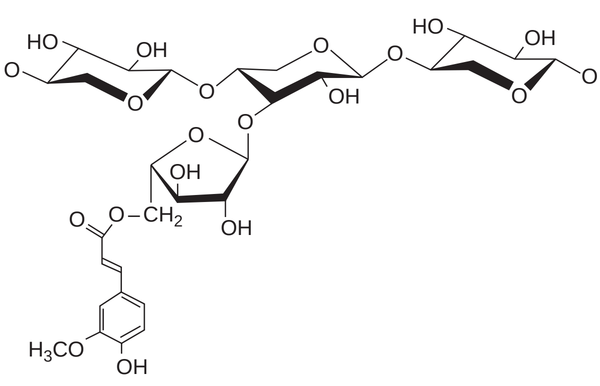

Figure 5 Structure of portion of a (1→4)-*β*-D-xylan chain substituted at *O*3-L-arabino of one residue with a 5-*O*-*trans*-feruloyl-L-arabinofuranosyl substituent. (Reproduced with permission from Fincher GB and Stone BA (1986) Cell walls and their components in cereal grain technology. *Advances in Cereal Science and Technology* 8: 207–295.)

(Figure 6). In region I, isolated unsubstituted Xyl*p* units are separated by one or two mono- or di-substituted units. The region II contains high amounts of Ara*f* units linked at C(O)3 and region III contains high amounts of contiguous (up to 6 and possibly more) unsubstituted Xyl*p* units.

Other monosaccharides found on the xylan backbone include D-glucuronic acid (GlcA*p*) and its 4-*O*-methyl ether, linked to the C(O)2 of Xyl*p* units. GlcA*p* units are found on endosperm and bran heteroxylans of rice and sorghum, and on bran heteroxylans of wheat, rye, and maize. The barley husk arabino-xylan has 4% by weight GlcA*p*. Various oligomeric chains are also found as substituents on arabino-xylans (Table 3).

Characteristically, a proportion of the Ara*f* units in the arabino-xylans of cereals, grasses, and several other families of monocotyledons, are esterified with the hydroxycinnamic acids, ferulic acid (FA), and to a lesser extent, its nonmethoxylated analogue *p*-coumaric acid (*p*CA) (Figure 5). These hydroxycinnamates are found at C(O)5 of Ara*f* units that are linked to C(O)3 of the Xyl*p* units. Hydroxycinnamates constitute 1.8% (w/w) in walls of wheat aleurone cells and the FA : *p*CA ratio is 9 : 1. In contrast, walls of the starchy endosperm cells contain only 0.04% (w/w) FA, with a trace of *p*CA.

During wall formation enzyme-catalyzed, radical (oxidative) coupling of feruloyl units on neighboring arabino-xylan chains occurs, and leads to their cross-linking. At least five different cross-linking ferulic acid dehydrodimers are encountered in fiber from wheat, barley, rye, spelt, oats, rice, and millet. Their structures are shown in **Figure 7**.

In walls of pericarp and seedcoat tissues, dehydrodiferulate bridges also cross-link arabino-xylans and in lignified walls the arabino-xylans are cross-linked to lignin through ferulic acid and dehydrodiferulate ester–ether bridges (Figure 8). Thus, the lignified walls in the pericarp–seedcoat layers and husk of cereal grains contain significant concentrations of lignin-heteroxylan complexes. Wheat bran, which consists largely of pericarp–seedcoat and aleurone, contains 0.09–0.18% (w/w) diferulate residues. This arises almost exclusively from the pericarp–seedcoat, because the contribution of FA dimers from the aleurone is very low (0.03% w/w).

The heteroxylans in maize bran contain 1.3% (w/w) dehydrodiferulates, which represents ~15 dehydroferulate cross-bridges per heteroxylan molecule. Lignin–heteroxylan associations through ester–ether FA and di-FA cross-links also occur in lignified walls in stem tissues of cereals and grasses.

In walls of wheat aleurone, highly-branched arabino-xylan appears to be covalently associated with protein, possibly through ester-linked FA that is linked to tyrosine in wall proteins by radical

coupling. Heteroxylans in maize and rye brans are also covalently associated with protein. The covalent bridges between heteroxylans, wall proteins, and lignins are important determinants of the cohesiveness of the wall fabric and of the resistance of lignified walls to digestion by polysaccharide and ester hydrolases.

Molecular Parameters

Average molecular masses of cereal heteroxylans range from 65 000 to 5 000 000 (DP 500–38 000) and, as is the case with the (1→3, 1→4)-*β*-D-glucans, the value depends on the cereal species, cell-wall type, extraction procedure, and the method used for molecular mass determination. The cereal heteroxylans are highly polydisperse with respect to molecular mass as indicated by M_w/M_n values that range from 1.3–4.2 for alkali-soluble wheat arabino-xylan, 4.1 for water-extractable wheat arabino-xylan, and 8.5 for rye arabino-xylan.

Solution Properties

As with the (1→3, 1→4)-*β*-D-glucans, a portion of the arabino-xylans from walls of cereal grains is soluble in water at 40°C and higher temperatures, but other extractants are required to bring all the arabino-xylan into solution. Whereas 0.05 M Na_2CO_3, 8 M urea, and dimethylsulphoxide extract only a small part of the water-insoluble arabino-xylan, most can be extracted with 1 M NaOH, 1 M hydroxylamine hydrochloride, saturated $Ba(OH)_2$ or 4-methylmorpholino-N-oxide. Of these, saturated $Ba(OH)_2$ containing $NaBH_4$ is the most successful extractant. Oxidative degradation with chlorite or alkaline H_2O_2 is effective in extracting arabino-xylan cross-linked to lignin from cereal brans. Arabino-xylans extracted under alkaline conditions may lose all or part of their acetyl and hydroxycinnamate substituents.

Solid-State and Solution Conformations

Unsubstituted (1→4)-*β*-D-xylans can adopt a twofold, helical conformation with only one hydrogen bond (O5′–H-O3′) between adjacent Xyl*p* units. This conformation is more flexible than the twofold helix of the (1→4)-*β*-D-glucan, cellulose, which has two hydrogen bonds (O2′–H-O6′ and O5′–H-O3′)

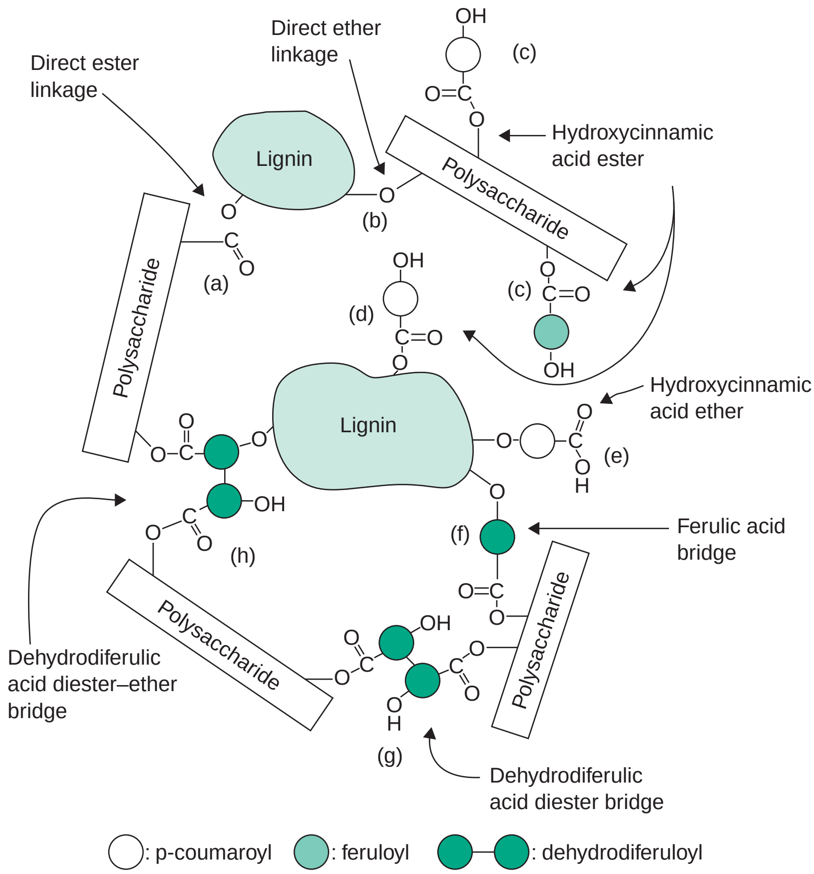

Figure 8 Schematic diagram showing possible covalent cross-links between polysaccharides and lignin in walls. (○) *p*-coumaric acid; (●) ferulic acid; (●–●) dehydrodiferulic acid. between adjacent glucosyl units (Figure 3b). The absence of cooperative inter-residue associations in xylans allows the molecules to be conformationally more versatile. Indeed, in the solid state the unsubstituted (1→4)-*β*-D-xylan chain preferentially exists as a fully-extended, threefold (i.e., three Xyl*p* units per helical turn), left-handed helix or a "slowly twisted ribbon" (Figure 9a). Ara*f* substitution of the backbone Xyl*p* units does not substantially change the basic threefold helical conformation (Figures 9b and 9c). However, substituted xylans cannot assume the twofold helical conformation because of significant steric interactions between the Ara*f* units and the xylan backbone. Nevertheless, (1→4)-*β*-D-xylans with low degrees of substitution interact reversibly with the surfaces of cellulose microfibrils and may do so in the twofold helical conformation. With increased Ara*f* substitution the affinity for cellulose decreases, presumably due to the increased incidence of the threefold helical conformation, which would be unfavorable for association with cellulose and because of the steric hindrance to interaction imposed by the substituents themselves.

The length of the backbone chains of arabino-xylans is ~3–5 nm. In solution, the arabino-xylans behave as partially stiff, worm-like, cylindrical molecules whose flexibility is largely unaffected by Ara*f* : Xyl*p* ratios, which are generally in the range 0.39–0.82 : 1.

Solution Properties

The intrinsic viscosities of wheat arabino-xylans range from 0.8 to 5.5 dl g^{-1}, depending on the degree of substitution. These values may be compared with 0.21 dl g^{-1} for dextran, 0.19 for beet arabinan, 0.12–0.25 for gum arabic, and 4.6–6.9 and 2.0–9.6 for barley and oat (1→3, 1→4)-*β*-D-glucans, respectively. The behavior of the arabino-xylans in solution is influenced not only by the overall asymmetry of the molecules and their DP, but also by the specific arrangement of Ara*f* units along the xylan backbone.

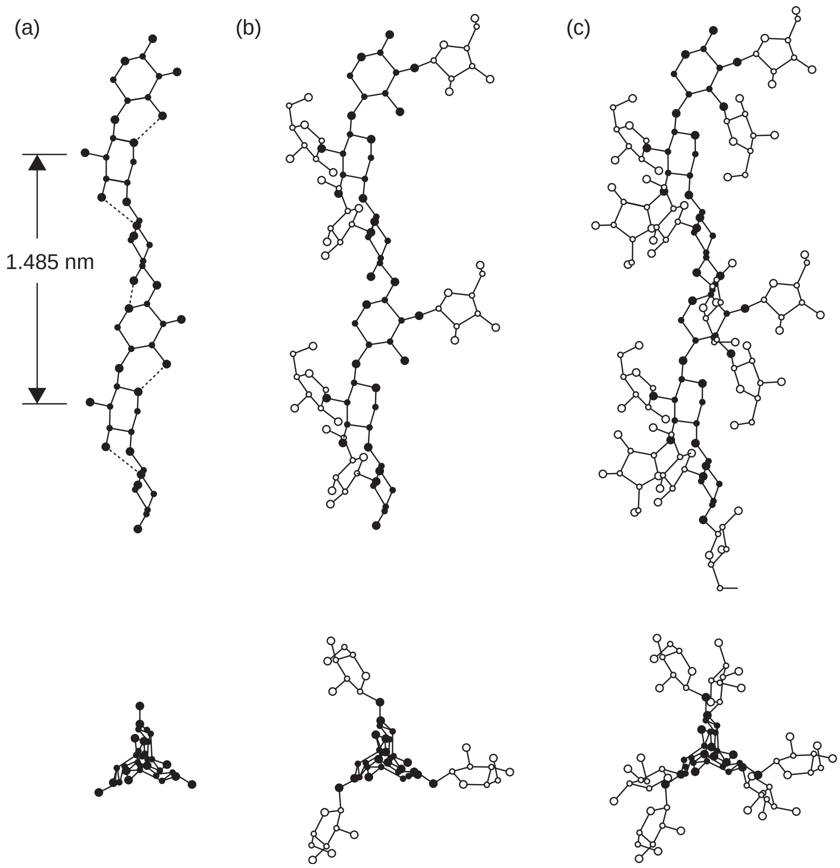

Figure 9 Arabino-xylan conformations. Projections perpendicular (top) and parallel (bottom) of (a) (1→4)-β-D-xylan backbone, (b) backbone with single arabinofuranosyl side groups, and (c) backbone with two arabinofuranosyl side groups. Hydrogen bonds are shown by dotted lines. In each case the backbone is a left handed, threefold helix. (Reproduced with permission from Atkins EDT (1992) Three dimensional structure, interactions and properties of xylans. In Visser J, Beldman G, Kusters-van Someren MA, and Voragen AGJ (eds.) (1992) *Xylan and Xylanases*, 576pp. Amsterdam: Elsevier.)

Thus, stretches of unsubstituted Xyl*p* units may permit intermolecular alignment over these sequences and lead to formation of chain associations that are stabilized by hydrogen bonds.

As with (1→3, 1→4)-β-D-glucans, the properties of arabino-xylan solutions are strongly concentration-dependent. At low concentrations, their viscosities are not shear-dependent but become so at higher concentrations. This behavior is typical of polysaccharides with extended, asymmetric conformations. Removal of Ara*f* units, either by dilute acid or by α-L-arabinofuranosidase action, leads to aggregation and precipitation of the residual (1→4)-β-D-xylan or of partially substituted arabino-xylan molecules.

Gelation

At high concentrations, arabino-xylan solutions form thermo-reversible gels that are stabilized by noncovalent interactions. Gelation of arabino-xylan solutions can also be induced by dimerization (cross-linking) of feruloyl units on neighboring arabino-xylan chains by radical coupling (Figure 7). The dimerization can be catalyzed by peroxidase / hydrogen peroxide, manganese-dependent peroxidase, laccase, ammonium persulfate, ferric chloride and other metal chlorides, halogens, linoleic acid/lipoxygenase, but not by iodate or bromate.

Well-developed, three-dimensional gel networks are obtained with arabino-xylans containing high FA contents, high molecular masses, and relatively unsubstituted xylan backbones. The latter facilitate the initial contact between feruloyl groups on neighboring arabino-xylan chains. The rate of gelation depends on temperature, pH, and concentration of oxidizing agent. The gel-forming abilities of water-extractable arabino-xylans from rye and barley are higher than for those from wheat and triticale. Covalently cross-linked arabino-xylans may hold up to 100 g water per 1 g polysaccharide. Gels formed by treatment of maize bran with peroxide/peroxidase

are brittle, probably due to the high content of cellulose.

Structure–Function Relationships in Cereal Processing and in Nutrition

Arabino-xylans, together with (1→3, 1→4)-β-D-glucans, contribute to wort and beer viscosity, which may impede wort separation and beer filtration. Arabino-xylans are also components of some beer hazes.

The water-soluble arabino-xylans in barley, rye, and wheat contribute an "antinutritive" effect in dietary formulations for poultry. In human diets, cereal arabino-xylans are components of the dietary fiber fraction. Water-extractable fractions from rye, wheat, and spelt (*Triticum spelta*) are mainly arabino-xylan, whereas those from barley and oats are mainly (1→3, 1→4)-β-D-glucans. Ingestion of arabino-xylan-enriched, wheat flour by-products reduces the glucose response following a meal in normal subjects. Water-extractable cereal fractions have a very low content of dehydrodiferulate and are partially fermented by anaerobic bacteria in the colon to produce short-chain fatty acids. Water-unextractable cereal fractions contain variable proportions of dehydrodiferulate; maize and millet have the highest content and oat wheat and spelt the lowest. Water unextractable cereal fractions are poorly fermented in the colon which may be related to the relatively high diferulate cross-linking of arabino-xylan chains that prevents swelling and attack by bacterial polysaccharide hydrolases. High concentrations of water-unextractable fractions in the diet are effective in increasing stool weight, through its bulking capacity.

Arabino-xylans have well-demonstrated impacts in bread making. Added water-extractable arabino-xylans have positive effects on the water absorption of doughs, especially after oxidative gelation, and also enhance loaf volume. In both cases, the amounts and molecular masses of the added arabino-xylan are important. Added water-extractable arabino-xylans are reported to slow starch retrogradation and to produce less firm breadcrumbs. The effect on breadcrumb texture is attributed to the increased moisture content of the samples. Water-extractable arabino-xylans from wheat bran are good emulsion stabilizers. They increase the strength and elasticity of gluten-starch films surrounding gas bubbles in doughs. This leads to a higher retention rate of CO_2 in the bubbles and produces a positive effect on the fineness and homogeneity of crumb texture. On the other hand, water-unextractable arabino-xylans have detrimental effects on dough rheology and loaf volume. Water-extractable rye arabino-xylans are inhibitors of ice crystal growth and are thus candidate cryostabilizers. Arabino-xylan–lipid mixtures may be cast as films.

Analysis and Detection

The determination of arabino-xylans in cereal and cereal products relies on the phloroglucinol–HCl or orcinol–HCl colorimetric reactions that show a high, but not absolute, specificity for pentoses. In addition, NIR can be used to estimate arabino-xylan content in grain and NIR peak intensity ratios at 1164 and 990 cm^{-1} allow the degree of Ara*f* substitution in arabino-xylans to be defined. Arabino-xylans in grain tissues can be sensitively detected by UV-induced, bright blue fluorescence (λ_{max} 415–445 nm, excitation 310 nm) due to esterified FA residues. Lignins also fluoresce under UV irradiation but may be distinguished from ferulate esters by examining walls at a high pH; where the lignin continues to fluoresce blue, but ferulate esters fluoresce green. Arabino-xylans may also be located in tissue sections through immuno-gold labeling with polyclonal antibodies raised against 4-O-methyl glucuronoxylan or arabino-xylan, or with gold-labeled xylanases. Polyclonal antibodies raised specifically against highly or sparsely substituted glucuronoarabinoxylans can also differentiate these types of arabino-xylan in cell walls.

Genetics

Despite the availability of high-density genetic maps for barley, no QTLs for arabino-xylan (or pentosan) content in barley are recorded in the major databases. However, a QTL accounting for ~35% of variation in both Ara*f* : Xyl*p* ratio and extract viscosity has been found on the long arm of chromosome 1B of bread wheat. The observation that there is no apparent change in arabino-xylan concentrations in the wheat 1BL/1RS translocation lines suggests that the genes involved are located outside the segment of that chromosome that was introgressed from rye. A total of five QTLs controlling acid detergent fiber (ADF) have been identified in barley and although ADF consists predominantly of cellulose and lignin from the pericarp–seedcoat, some of the effects might be related to arabino-xylan and/or (1→3, 1→4)-β-D-glucan content. Three QTLs, with relatively large effects, map close to one another on chromosome 2H, whereas the other two QTLs are on chromosomes 4H and 1H.

Glucomannans

Glucomannans are linear copolymers of β-D-glucopyranose (~30%) and its 2-epimer, β-D-mannopyranose (~70%), joined by (1→4)-linkages (Figure 10a) to form linear chains with DPs ranging from less

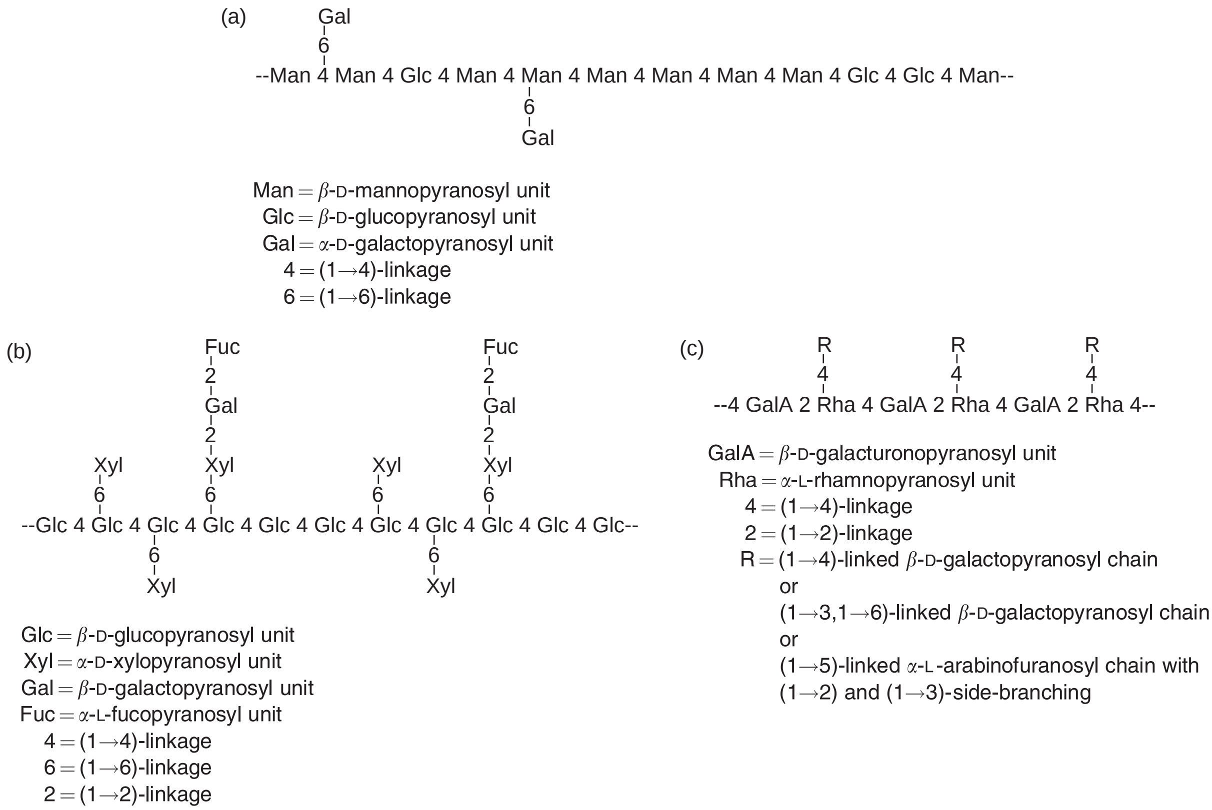

Figure 10 Structural features of three noncellulosic polysaccharides found as minor constituents in cell walls of cereal grains: (a) glucomannans, (b) xyloglucans, and (c) pectic polysaccharides.

than 100 to several thousand. In some examples, the backbone has (1→6)-linked β-D-galactopyranosyl substituents and is generally esterified with acetyl groups. The shape of the glucomannan polymer is similar to cellulose (Figure 3a) and it has therefore been suggested that the chains may associate strongly with surfaces of cellulose microfibrils. The glucomannans are extractable from walls with alkaline borate solutions that act by complexing with the mannopyranosyl units.

Glucomannans are minor constituents of walls of most aleurone and starchy endosperm cells of cereals (Table 1), but in certain *indica* rice cultivars the endosperm walls contain up to 17% glucomannan.

Xyloglucans

Xylo-(1→4)-β-D-glucans (heteroglucans) are a family of side-chain-branched heteroglycans (Figure 10b) consisting of a cellulose-like (1→4)-β-D-glucan backbone side-branched at regular intervals by α-D-xylopyranosyl units at C(O)6 of the glucosyl residues. Some side-branch xylosyl units carry β-D-galactopyranosyl and α-L-fucopyranosyl substituents. Compared with xyloglucans from dicotyledonous plants, those from grasses are less substituted with xylose, contain little galactose, and have stretches of unsubstituted backbone. Xyloglucans have DPs of 600–700 and readily associate with surfaces of cellulose microfibrils. After extraction with dilute alkali, they are water-soluble. Xyloglucans are generally considered to be of minor significance in walls of cereal grain tissues, although procedures used in earlier analyses may have underestimated their relative abundance in wall preparations.

Pectic Polysaccharides

The pectic polysaccharides are a diverse group of side-chain-branched heteroglycans. The backbone is a copolymer of alternating (1→4)-linked α-galacturonosyl and (1→2)-linked α-L-rhamnopyranosyl units (Figure 10c). The rhamnogalacturonans are variously side-branched on the rhamnosyl units by arabinan, arabinogalactan, and more complex branched oligosaccharides. In addition, variable amounts of (1→4)-α-linked homogalacturonan may be present in the same backbone chain. There is also variable methyl esterification and hydroxyl acetylation of the galacturonosyl units.

The homogalacturonan domain complexes with Ca^{2+}, which promotes gelation by forming Ca^{2+} bridges between unesterified galacturonosyl units on adjacent chains. Pectic polysaccharides are minor constituents of the walls of vegetative tissues and grains of cereals, although measurable amounts have been reported in walls of rice endosperm cells (Table 1).

Callose

Callose is a (1→3)-β-D-glucan. Like cellulose, it is a linear homopolymer and is insoluble in water. However, callose is soluble in dilute NaOH. Callose can be recognized in tissue sections by an intense yellow, UV-induced fluorescence (λ_{max} 495 nm, excitation 380 nm) when associated with the aniline blue fluorochrome, a sulphonated 4,4′-dianilinobenzophenone, or by its binding to a specific monoclonal antibody. In mature barley endosperm, callose occurs as small bead-like deposits on the inner surfaces of walls throughout the starchy endosperm but especially at the aleurone/subaleurone interface. The deposition of callose is a well-known consequence of stress and wounding. Thus, the endosperm deposits may arise as a consequence of plasmolysis during the drying of the grain. The callose content of barley endosperm wall preparations is ~1%. Callose is found in the developing walls of rice endosperm during the early stages of cellularization, but is not a component of mature walls. It is also found in the nucellar projection and in the vascular tissue of the crease of developing barley, but at maturity remains only in the vascular tissue. In the nucellar projection and the vascular tissue, callose deposition might be related to the control of assimilate transport into the developing endosperm.

Fructans

Fructans from cereals consist of short chains of up to 4–5 β-D-fructofuranosyl units in (2→6)-β-linkage to the fructosyl residue of the disaccharide sucrose. Some branching through (2→1)-β-linkages may also occur. Cereal fructans are soluble in water and in boiling 80% (v/v) ethanol. During the early development of wheat grain, fructans can account for as much as 20% dry weight. In mature grains, the contents are low and variable: wheat, 1.3–2.5%; rye, 4.6–6.6%; barley, 0.8%; and oats, 0.1%. In the grain, fructans are found both in the endosperm and the pericarp/embryo, with higher concentrations in the latter fraction. Fructans are important carbohydrate reserves in the vegetative tissues of temperate cereals, particularly in young seedlings where they can account for 70% of the dry weight.

Cereal fructans are not digested in the monogastric stomach or small intestine but are readily fermented by microorganisms in the lower gut. Thus, they may be considered to be part of cereal dietary fiber. Fructans may be quantified by NIR or by a specific enzymatic procedure, and their size distribution determined by HPLC or MALDI-TOF-MS.

Arabinogalactan-Proteins

Arabinogalactan-proteins (AGPs) are widely distributed in plants. They consist of a protein backbone that is rich in hydroxyproline and to which arabinogalactan polysaccharides are covalently attached. In wheat grains, the major AGP is an arabinogalactan-peptide, with a peptide backbone that is much smaller than most AGPs. The arabinogalactan-peptide from wheat flour constitutes 0.27–0.38% on a dry-weight basis and has an average molecular mass of 22 000, although higher molecular mass AGPs have been detected in other cereal grains, including barley. The polysaccharide portion of the wheat arabinogalactan-peptide constitutes 92% of the molecule, and consists of branch-on-branch, β-D-galactosyl units (Gal*p*) linked by (1→3)- and (1→6)-linkages (Figure 11). The branched

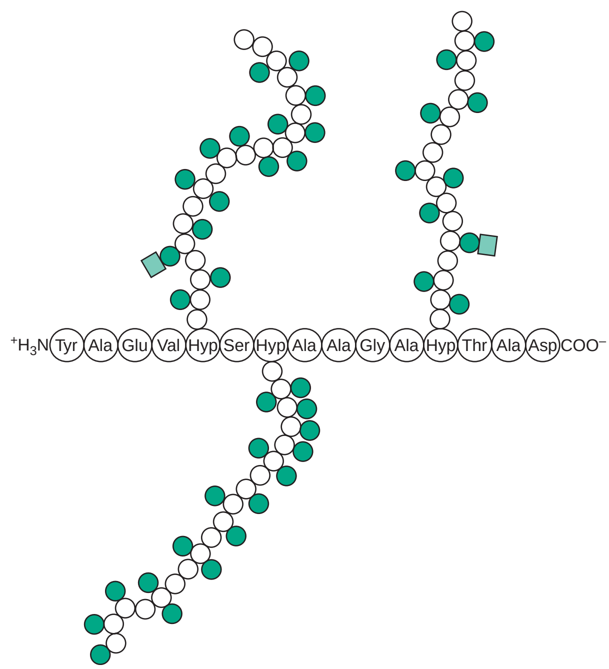

Figure 11 Structure of wheat arabinogalactan-peptide. (○) (1→3)-linked-β-D galactopyranosyl unit, (●) (1→6)-linked β-D-galactopyranosyl unit, and (■) terminal α-L-arabinofuranosyl unit. (Structure based on data of Fincher GB, Sawyer WH, and Stone BA (1974) Chemical and physical properties of an arabinogalactan-peptide from wheat endosperm. *Biochemical Journal* 139: 535–545 and Van den Bulck K, *et al.* (2002) 79: 329–331.)

β-D-galactan backbone is substituted by single α-L-arabinofuranosyl units. The arabinogalactan has an Ara*f*:Gal*p* ratio of 0.63–0.72:1. In wheat endosperm, the arabinogalactan component of the molecule is covalently linked to a peptide of molecular mass 7800 at each of the three hydroxyproline residues in the peptide sequence. The same peptide sequence is found at the NH_2 terminus of a protein associated with the surface of wheat starch granules. Among eight Canadian wheat cultivars, the peptide constituted between 6.5% and 14.3% of the AG-peptide molecule.

The wheat AG-peptide is very soluble in water and is not precipitated at saturating ammonium sulfate concentrations. Its solutions are of low intrinsic viscosity ($0.045-0.062\,dl\,g^{-1}$). Neither its subcellular location in the endosperm nor its physiological function are known. The wheat AG-peptide, unlike its larger AGP counterparts, does not bind to the phenylazo dye, β-glycosyl Yariv reagents. The effects of wheat AG-peptides on bread-making properties are of equivocal significance.

Concluding Remarks

There is a great deal of information available on the chemistry of nonstarch polysaccharides in cereal grains. This is directly attributable to the central importance of these polysaccharides in large-scale food processing activities that include brewing, baking, and stock feed manufacture. Moreover, the nonstarch polysaccharides of cereals have attracted renewed interest in recent years because of their potentially beneficial effects in human nutrition. Despite this interest, there remain major gaps in our knowledge of the genes and enzymes that control nonstarch polysaccharide biosynthesis in the cereal grain. It is likely that large scale, high throughput functional genomics programs, many of which are focused on cereal quality determination, will soon lead to the identification of the genes and enzymes responsible for (1→3, 1→4)-β-D-glucan and arabino-xylan biosynthesis in developing cereal endosperm, and eventually to an understanding of the factors that control fine chemical structure of the polysaccharides. This information can be confidently expected to provide valuable molecular markers through which breeders will track key genes in their breeding programs and improve quality characteristics related to nonstarch polysaccharides in commercially important cereals.

Acknowledgments

The authors thank D. Mather, J. Dufour, and K. Valenta for assistance in the preparation of material for this manuscript. We are grateful to Dr. D. Mares and Dr. P. Harris for their comments on the manuscript. Grain Defects

S A Barton, Oxford Agricultural Trials Ltd, Oxford, UK

Introduction

This article begins with a brief introduction to the stages through which grain travels from field crop to commodity. Similar symptoms may result from more than one cause. Therefore, it is important to be familiar with normal, healthy cereal grains before trying to recognize defects in them. The recognition of defects that are important to merchants or processors who buy the grain is explained with examples of how a poor raw material would affect an end product. An explanation of why certain defects result in sample rejection is provided where possible. Causes of physical and chemical defects are not always obvious; many result from pest infestation or disease infection earlier in the growing season of the crop. Grain defects that have not resulted from damage during development of the crop may be due to problems encountered at harvest, subsequent storage, or processing. Measures to prevent some of the main causes for rejected grain samples are suggested.

As there are other articles in this encyclopedia devoted to a cereal overview, descriptions of grain morphology, nutritional composition of grains, and diseases of various individual crops are intentionally kept brief.

Production of Sound Grain

Growth and Harvest

In order to recognize defective grain, it is first necessary to know the qualities of sound (healthy or intact) grain. Cereal crops can be defined as any plants cultivated for seed as human food, although they tend to include only crops closely related to grass. In most cases, they require physical processing (cutting and threshing, or combining) to remove individual grains from the spike or ear in which they have grown. Barley, millet, oats, rice, rye, triticale, and wheat have grass-like grains when harvested. The seed of maize and grain sorghum is produced on larger, sturdier plants that are less grass like and better adapted to climates with brighter sunlight. Barley and the majority of oat varieties retain their husks when threshed, although several varieties of naked oats are also available whose husks are removed when they are harvested. The other cereals require threshing to remove their husks at harvest, prior to storage. Barley, oats, rye, triticale, and wheat all have a crease on one side of their grain as a result of the way in which they develop. It is this complication in grain morphology that has led to the evolution of a complicated milling process to extract white flour from wheat. The more uniform shape of other grain-producing plants allows them to be processed more simply.

Drying

When cereals are grown in the temperate European climates where summer weather cannot be guaranteed to be dry, it is often necessary to reduce the moisture of grain once it has been harvested from the field. This can be done by a range of methods involving the flow of air through the grain, causing it to dry out. The air temperature may be raised in

order to speed up the drying process, but if an internal grain temperature of 60°C is exceeded, there is a risk of protein denaturation. Drying at high temperatures can damage germination potential. The grower must ensure that the grain is dried enough to reduce or prevent fungal growth during storage (usually below 15% moisture content). The crop may be stored on the farm by the grower or sold on to a merchant or cooperative and bulked up with other similar types of grain. In drier climates, premature ripening may occur due to stress from drought. In such cases, grains are unlikely to reach their full potential size.

Storage

The reason why cereal grains are so attractive to humans for food is because they have pleasant flavor, high nutritional value, and versatility. It is not surprising then that a number of pests have developed to exploit grain at whatever stage of production they are able to gain access to it. Assuming a grain crop has been protected during growth and has been successfully harvested into a clean storage area, it must then be protected from marauding birds, rodents, and insects. Secure grain silos or barns, which protect against pest invasion, are necessary. In addition to this, the temperature and humidity of the produce must be kept to suitably low levels to prevent conditions suitable for storage fungi, mites, and insect pests. In this way, even if the store is breached, the environment within the grain will not allow it to be spoiled. Regular monitoring of the store conditions, particularly the temperature, is vital. If a problem is to be dealt with in a timely and effective manner, its early detection is vital. Specific and detailed information may be found in the article on harvesting, storage, and transport of barley.

Detection of Grain Defects

Sampling

Defects are assessed at intake points where grain consignments are delivered to the buyer or merchant, prior to processing or bulking with other samples that have been produced independently. Sampling correctly is vital as a precursor to any type of assessment in order to ensure that the original load is being correctly represented (Figure 1).

It is worth taking time to appreciate the importance of this aspect of grain management. If a scoop full of grains were to be removed from the top of the sample after it has been transported to the intake point, the lightest and least dense material would be removed, rather than a mixture of the whole consignment. This is likely to contain unthreshed grains, broken grains, weed seeds of similar size, but lower density to the crop, ergot and insects as well as some healthy, but lighter crop grains. By analyzing such a sample, the bulk load may be rejected without having had a fair trial. If a subsample were taken from the bottom of the bulk load, it would be likely to contain the most dense and heaviest fractions, including stones, heavy dust, and small, dense weed seeds as some of the heavier (larger) crop grains. Analysis of this sample could produce results indicating the whole load to be of better quality than it really is. To avoid such misrepresentations, a strategy for accurate sampling is necessary.

A sample for analysis should consist of several individual subsamples taken with a sampling spear that penetrates the entire depth of the transport container, at intervals across it. These subsamples should then be thoroughly mixed and subdivided in order to give a suitably sized sample for analysis. The subdivision should be carried out in such a way as to keep the

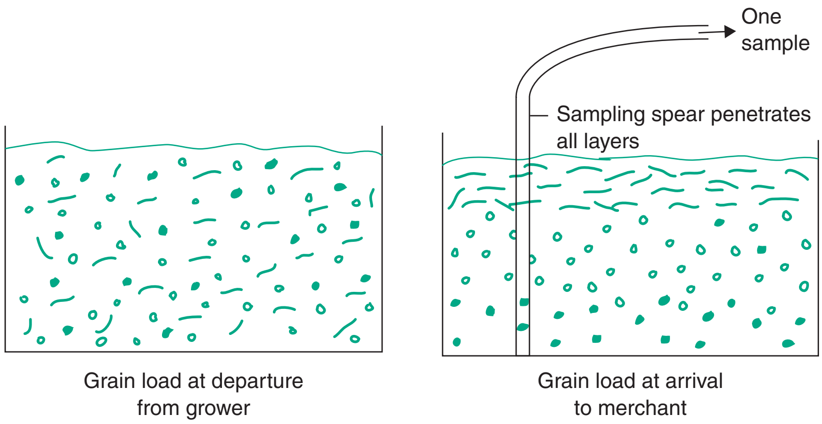

Figure 1 Stratification of grain during transit and sampling spear.

sample representative of the entire bulk. The use of a grain splitter enables this process to be carried out quickly and efficiently (Figure 2). The sample is tipped into the top of the splitter and half is diverted into one collection tray, the other half into the second tray. A number of tests are routinely carried out in order to check for grain suitability; these are outlined here, but explained in detail in the article on analysis of cereal quality.

Visual Assessment

Once a representative sample has been obtained, an evaluation by a trained individual is the quickest and most effective way to identify many potential defects. With experience, it is even possible to identify differences between varieties or quality types of the same cereal at this stage.

Sample appearance The kernels themselves should appear healthy and fit for purpose; generally they should be intact (with no sign of having started to germinate), bold (not shriveled), and bright (not dull or dead looking). If there is evidence that germination (or sprouting) has occurred, even if it has stopped, this is an indication that problems could arise during processing. In bread-making wheat, this would be as a result of excess enzyme activity from the germination process, or in malting barley, prevention of further growth during malting. Skinned barley grains cannot be fully malted and are not acceptable for malting samples; the condition occurs during harvesting, when all or part of the protective covering layer (husk) is torn away. Similarly, broken grains occurring during harvest will reduce the quality of any cereal sample, as they will be removed during cleaning.

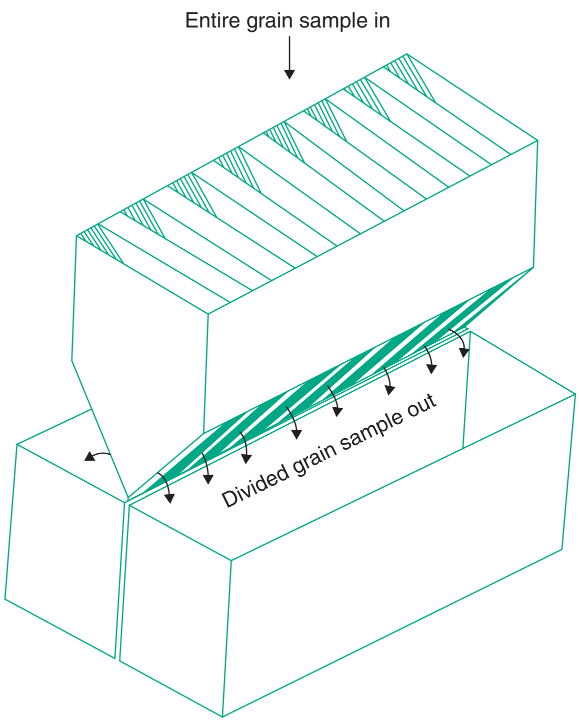

Figure 2 Sample division using a grain splitter.

Sample purity Sample purity is particularly important where the purchaser has set specific requirements. Although contaminants may not relate directly to the integrity of the grains themselves, they provide the main contribution to impurities within the sample. Easily visible signs of contamination include broken grains, ergot, insects, unthreshed grains, other cereal grains, weed seeds, soil, and stones. Dividing a predetermined weight of grain into grain and non-grain material is used as an objective measurement of impurities within a sample. Each category of non-grain material is then weighed and expressed as a percentage of the total sample. This type of assessment is particularly important for high-quality crops such as the high-protein bread-making wheats produced in Australia, Canada, and the USA. Contaminants mixed in with grain consignments can be the cause of reduction in price paid by the purchaser, or in outright rejection of the sample. Although the majority of contaminants can be removed by cleaning the grain, the cost of this (to the processor) together with the cost of waste disposal must be recoverable in the final product market price or discounted when purchasing the grain.

Grain should be free from pests (live or dead); if adults are present, they will be obvious during the visual appraisal, but certain larvae develop within stored grain, with the only indication to their presence being a small hole in the side of the affected kernel. The sense of smell can be used to detect odors, which may be symptomatic of mold (musty), mite infestation (minty or sour), or animal droppings; none of these should be present.

Discoloration If a pale, uniform product is to be made from the raw material, it is important that the entire sample is uniformly clean and does not contain discolored grain. Grains may become brown in places either as a result of physical "bin burning" or fungal staining (black point). The latter is particularly noticeable in whiter types of wheat such as the Australian Prime Hard, and its severity is associated with cereal variety. The germ end of the kernel becomes darkened, varying from a pale watermark to almost black, the affected area ranging in size from a small speck to covering over half of the grain.

A proportion of unripe, green grains may be present in the sample. Field fungi that have remained on the grain after harvesting may produce either pink (*Fusarium* species) or black (sooty molds) areas on the grain. The presence of black mold in malting barley samples is potentially problematic, as the malting process is carried out under conditions which may encourage the proliferation of these fungi. Storage fungi that have developed after harvest may cause blackening and a musty sour smell. Again, it is important to be familiar with the crop in question, as the color of healthy grain is not always golden; for example, sorghum grains naturally ripen to a great variety of colors.

Grain Analysis

Specific weight This measurement of grain density is the weight of the grains that exactly fill a defined volume (generally the weight in kg of a sample calculated to fill 1 hl or 20 l) and it takes into account the type of cereal grains being measured. If samples contain a high proportion of small, unthreshed, or damaged grains, or if the moisture content is high, the grains will not pack efficiently and will give a low specific weight. If grains are larger, dry, and undamaged, they will give a higher specific weight. There will be some variation between seasons due to the weather and other environmental factors, also between different varieties, or types of each crop. Merchants and cooperatives will generally set acceptance values, below which a discounted price may be paid to the grower or the load may be rejected as unfit for use.

Moisture If a sample is too wet, it will not be safe to store for any length of time without risking rapid deterioration of quality. The most commonly used method for its determination at grain intake is by near-infrared reflectance (NIR); this indirect method is calibrated using the oven moisture method. The moisture content is simply the amount (weight) of moisture present in a sample expressed as a percentage of the initial weight. The oven moisture method involves weighing a sample accurately, drying it under specified conditions, and weighing the dried sample. The calculation of the moisture can then be made as the difference in weight divided by the initial weight and multiplied by 100 to give it as a percentage. High moisture content is the precursor to many problems within grain, including growth of storage fungi, pest infestation, and germination. Although the acceptable moisture of a sample will be agreed between a producer and merchant, generally, if a consignment of grain is too wet, it will require drying before it is fit to be processed further. If a sample is dry, it will store well, but may require the addition of large quantities of water over a long period of time to enable processing (particularly in the case of milling wheat). Also, dry grain will weigh less than the same quantity of wetter grain; this means that the grower will effectively be selling the produce at a lower price as price is based on weight, not number of grains.

The support of fungal growth by moist conditions is of particular concern in connection with mycotoxin production. The presence of the wrong sort of fungi in warm damp conditions can lead to them producing toxic substances such as ochratoxin. By ensuring that the moisture content is kept suitably low, the conditions needed for the production of mycotoxins are prevented from occurring.

Protein The percentage protein content of a sample of cereal grains is likely to be an important factor in determining its sale value. At grain intake, a rapid protein measurement is taken with a suitably calibrated instrument. The amount of protein present is expressed at a specified moisture content, an example might be 13% protein on a dry matter basis (i.e., at 0% moisture). For the majority of grains, the higher the amount of protein (or nitrogen) present, the better, although, for malting barley, a lower nitrogen content is preferred as this indicates a higher carbohydrate content. The protein quality is also important when considering bread-making wheat types; if the specification for this is not met, the consignment will not be suitable for processing into bread. In order to ensure that a consignment of wheat is only accepted if it is suitable for processing, there are various tests that could be carried out. The simplest of these is the gluten-washing or wet gluten test. The starch is washed out of a ground wheat sample (using water or weak salt solution) and the remaining gluten is checked for color, elasticity, and extensibility.

Starch This is the main component of cereal grains; in some crops it has the highest value of all components. In wheat it is important during bread making as it is broken down by enzymes (α-amylase in particular) to feed the yeast during the baking process and enables the production of gas to give a risen loaf. At the subcellular level, there are different types of starch granules that give different characteristics to the starch depending on the ratio in which they occur. Cornstarch (from maize) is an effective thickening agent; it is relatively easy to extract and gives a consistent product. Modified maize starch can be found on the ingredient list of many modern food products. Starch is also used in the preparation of paper, wallpaper paste, and many pharmaceutical products.

Enzyme activity Green wheat grains can have high levels of α-amylase activity. As wheat grains develop, the enzyme activity reduces to a minimum level around the time of harvesting when the grains reach maturity. During germination, enzyme level rises again as it is involved in the breakdown of starch granules into polysaccharides. The Hagberg falling number (HFN) method is used at grain intake as an indirect measure of wheat enzyme content and it is able to detect the very early stages of enzyme activity that have no visible external signs. High levels of the enzyme α-amylase will cause starch to break down into its constituent polysaccharides. When starch is mixed with water at high temperatures it forms a gelatinous paste, and the time taken by a plunger to fall through the mixture indicates the integrity of the starch present within the flour. If the plunger falls more quickly, it indicates that the starch has been broken down.

Causes of Grain Defects

Diseases

Black point Black point appears to be a response by the living tissue over the germ of the grain, to invasion or infection, whereby pigmented lignin precursors are laid down, blocking the progress of the invading mechanism. It has been linked to species of *Alternaria* by some work, but shown to be nonpathogen specific by other studies.

Bunt or stinking smut Spores of bunt (*Tilletia caries*) may be present in wheat grain samples as they are often released during harvesting if they were present within the crop. The fungus enters the germinated seedling and develops within the plant, resulting in misshapen grains that contain black, foul-smelling spores instead of white, starchy endosperm.

Ergot Ergots are the fruiting bodies of a fungal pathogen (*Claviceps purpurea*) that invades the developing florets of all grass species. It is spread by insects, rain-splash, or strong gusts of wind, then grows into the developing ovaries and gradually forms a solid purple-black mass that is often over twice the length of a normal grain. Ergotoxin is present within these fruiting bodies and, if ingested, can result in many unpleasant (if not deadly) symptoms including hallucinations, convulsions, abortion, and gangrene. Prevention is by the use of ergot-free grains or by burying any ergots from previous crops by deep plowing and crop rotation to prevent germination of ergots in the following year's crop.

***Fusarium* sp.** Pink grains often result from the infection of cereal ears by *Fusarium* sp., which will sporulate freely under the right conditions resulting in a salmon pink tinge to the grain. The mycotoxin "deoxynivalenol" (DON) is produced by *Fusarium* sp. when conditions are suitable. DON levels indicate the gushing (foaming) potential of beer.

Loose smut Florets of developing grain plants are infected with spores of *Ustilago nuda*; symptoms of infected plants include yellowing of the flag leaf and a covering of thick black spores over the entire ear. Seed dressing can be used to prevent reoccurrence in the following crop. Common smut of maize (*Ustilago maydis*) is more resilient to control, the best defense being choice of a resistant maize variety.

Environment

Drought During grain development, a certain amount of moisture is required prior to harvest to enable grain filling to take place. Under very dry conditions, grains will become severely shriveled and will be very small and light when they are harvested.

Frost damage Kernels that have been affected by frost may become thin and distorted with a blue-gray discoloration in severe cases.

Genetic and environment interaction The malformation of grains may be induced by a combination of genetic makeup and environmental factors. It was this that led to the sterility seen in the wheat variety Moulin in the UK in the 1980s.

Green grains The presence of green grains within a grain sample indicates either an early harvest, or a late wet period that stimulated the crop to produce back tillers that did not have sufficient time to ripen prior to harvest.

Sprouting (pregermination) Wet weather prior to harvest can have the effect of retarding ripening by keeping the crop green for longer and this may lead to the crop lodging (or falling down) due to the weight of the plants and the damp soil allowing roots to become loosened. Once areas of a crop have become lodged, the ripe, damp grains are prone to germination (or sprouting) whilst remaining in the ears. This process may be halted at the onset of dry conditions either in the field or due to drying of harvested seeds. The evidence that germination had begun remains visible to the trained eye, however, and should be picked up at sample intake.

Weed competition High populations of competitive weeds in crops will prevent them from realizing their full potential in terms of yield and grain size. Also, the presence of weed seeds within the yielded crop will add to impurities and reduce the quality of the grain yield.

Pests

Field insect larvae Orange blossom midge larvae enter the wheat floret before anthesis and live on the developing green grain. If the affected kernels reach maturity, they are shrunken and have a deformed, flattened (and often darkened) dorsal side.

Storage insect larvae Some storage pests ensure their survival by burrowing a hole into a cereal grain and laying a single egg in it; when the egg hatches, the larva is surrounded by a plentiful food supply. As it develops, the larva hollows out the grain, eventually leaving just a husk of bran without the starchy endosperm.

Crop Processing

Drying Heat damage of proteins due to incorrect drying is mainly a problem in bread-making quality wheat. The functional gluten proteins are denatured, which causes them to lose their extensible and elastic properties and may cause a darkening of the flour produced upon grinding the grain. Heat damage of barley can reduce the malting quality of the grain.

Harvesting Harvesting when too dry or with incorrect settings of the combine can lead to broken grains.

Storage Discoloration of grains known as "bin burning" occurs when stored grain remain in constant contact with silo walls heated in localized areas, for example, by sunlight on the outside of these walls.

Prevention of Grain Defects

By addressing the causes of grain defects outlined above, many of the symptoms can be reduced, but due to the nature of crop growth, they are unlikely to be eliminated. The careful selection of variety to suit the local environmental conditions, good husbandry in the field, management of diseases and pests both during field growth and storage, and care during harvesting and processing will ensure a healthy, good quality crop.

Published by Elsevier Ltd.

Introduction

Plant diseases are major constraints to crop production, affecting yield and quality. In extreme circumstances, contamination with pathogens or their metabolites can cause unpleasant odors and tastes, and in some instances, toxicoses of food and fodder products. Diseases can be subdivided into those with abiotic or biotic causes.

Abiotic diseases include mineral deficiencies and toxicities, and the effects of soil salinity, acidity, and alkalinity. In some instances, mineral deficiencies and toxicities can carry over to harvested products, and to the food and fodder products derived from them. Biotic diseases are caused by fungi, bacteria, nematodes, viruses, and mycoplasmas. Many farm management practices are aimed at alleviating the effects of disease through agronomic, chemical, and genetic means. It has been estimated that one-half of the cost of plant improvement involves "maintenance" breeding, i.e., breeding to maintain current yield and quality levels to meet

the challenges of degrading growing environments and evolving pathotypes of major pathogens.

This article will outline some of the internationally important diseases that affect cereal production and will emphasize those with greatest effects on commerce and endpoint quality.

Abiotic Diseases of Cereals

All plant species have an optimum range of soil conditions in which they thrive, and performance declines with digression from these optima. Marginal environmental conditions can be alleviated by cultural practices and fertilizers. Some species may be better adapted to prevailing conditions. For example, cereal rye and some triticale genotypes are tolerant to low pH (high aluminum) conditions. Within each species there is also a range of genetic variation that can be exploited in breeding programs, resulting in cultivars that perform better under specific nutrient regimes, e.g., cultivars more tolerant to low pH, or more tolerant to high or to low levels of soil boron or manganese. In these latter cases, mechanisms such as mineral exclusion that lead to a genotype's ability to tolerate high levels of a mineral, may be the basis of the poor ability of that genotype to tolerate a deficiency of the same mineral.

Mineral deficiencies are more easily rectified than toxicities. Generally, mineral fertilizers applied to the soil or leaves will overcome deficiencies even though breeding solutions may also be available. Toxicities can be alleviated by amelioration of the environment to reduce availability of the mineral or by selection and use of more tolerant genotypes. In many circumstances, more tolerant cereal species may be preferred.

In a broader context, disease-like symptoms may be caused by extreme or abnormal weather conditions such as drought, heat, and frost, as well as pesticides. Agronomists and farmers need to be able to distinguish symptoms of environmental stress from diseases caused by both abiotic and biotic agents. Finally, certain genetically determined "disease mimics" are expressed as physiologic spotting or blotching. These are more likely to be encountered in breeding populations than in released cultivars, as breeders obviously select against such phenotypes. However, they may appear in cultivars grown in environments different from those in which they were originally selected. Genetic analyses have shown that some forms of physiologic spotting involve single genes or the complementary interaction of unlinked genes.

Black Point/Kernel Smudge: Abiotic or Biotic Diseases?

Winter cereals, particularly those grown outside a classic Mediterranean climate, often encounter a complex of harmful weathering conditions during grain development. Winter crops in the subtropics, and summer crops in temperate climates, often ripen with high humidity or rain. High humidity alone can stall or prolong ripening, initiate germination, induce excessive enzyme activity, and establish colonization by saprophytic fungi and bacteria. In wheat, high humidity induces a clean edged symmetrical melanized pattern in the pericarp and testa cells covering the germ and adjacent areas. In barley, the glume tissue covering the germ may become melanized. Prolonged wet periods may smudge the melanization and induce vigorous saprophytic growth on the grain surface affecting its color and brightness. Pink pigments exuded from *Eppicoccum* spp. and sporulation of fungi such as *Cladosporium* spp. are often included in the black point/kernel smudge complex.

Grain can also be directly infected by foliar and root pathogens. For example, *Bipolaris sorokiniana* causes shriveling and browning of infected tissue in wheat and barley grain and *Phaeosphaeria avenaria* f. sp. *avenaria* causes similar symptoms in oats. *Pyrenophora tritici-repentis* and *Fusarium* spp. produce a pink pigment in wheat, often referred to as kernel smudge, and can invade the living aleurone tissue and attack the embryo.

Although various fungi are associated with black point/kernel smudge, there is no conclusive evidence that black point melanization is a direct result of fungal action. The often reported association between symptoms and the most common grain colonizer, *Alternaria alternata*, is not strong and several studies have been unable to confirm any link. Pigmentation first appears when the pericarp and testa cells are crushed to form the seedcoat and the grain begins to lose moisture. Prolonging or reversing the drying process allows interaction between enzymes and substrates that normally lie dormant until subsequent germination.

Black point melanization alone does not affect flour or end product quality of bread wheat. Recent research has shown that flour color and speckiness does not deteriorate despite black point levels of up to 10% and that black point only affects the bran, and that flour protein has a greater effect on flour color than does black point. Even with very high levels of black point, careful milling can extract flour with an acceptable color for most bread-making purposes. However, black point in durum poses a greater problem with many reports suggesting that low levels of black point can cause visible dark specks in pasta

products. Kernel smudge caused by saprophytic and/or pathogenic fungi is also an indicator of weather damage, and as such, can have a severe effect on grain quality and viability. Pink smudge caused by *Fusarium graminearum* may contain mycotoxins.

Under wet conditions, all cereal grains can develop symptoms of black point/kernel smudge, but only wheat, durum, barley, rye, and triticale produce black point melanization. However, similar discolorations are sometimes found in rice, sorghum, and other cereals.

While fungicide application has been used in some countries to control black point, there is little evidence of success. Genetic variation required to reduce or eliminate black point melanism has been identified in wheat, durum, and barley. However, despite variation, genetic improvement has proven very difficult due to a lack of understanding of the underlying mechanisms, the complexity of interactions with environmental factors, and a lack of reproducible and reliable screening techniques. Consequently, most breeding programs rely on opportunistic selection.

Significant Biotic Diseases of Cereal Grain Crops

An exhaustive list of all diseases of the major cereal grain crops is beyond the scope of this article. Some of the more important and widely dispersed diseases of wheat, barley, rye, oats, maize, and rice are listed in Table 1. However, numerous diseases of each crop and of triticale, sorghum, and millets that may be very important on a local, or even regional, basis have been omitted. Infection processes and groups of diseases based on means of infection will be discussed.

Triticale, a hybrid crop combining the genomes of tetraploid wheat and rye is more prone to the diseases of wheat than those of rye. Infection and spread of many diseases is enhanced by wet conditions and the use of cereal rye and sorghum and millets in areas considered too dry for wheat and barley, or corn, respectively, results in reduced risks of epidemics on those crops, in addition to the distinctive resistances they may possess.

Soil-Borne Diseases

True soil-borne diseases are probably relatively few in number as pathogens are more likely to be associated with decomposing plant material. Fungi such as the take-all pathogen, *Gaeumannomyces graminis* var. *tritici*, attacking wheat, and to a lesser extent, triticale and barley, can be considered to be soil-borne – or at least located below the soil surface – although they may be associated with the decaying residues of previous crops and certain grass species. The spores of a number of smut species can be soil-borne as a result of previously smutted crops. They are then available to infect the roots, crowns, and coleoptiles of germinating seeds. These include all of the bunts (except karnal bunt) and smut pathogens except the flower-infecting loose smuts of wheat, barley, and oats. Most nematodes survive in the soil before attaching to cereal roots. The most important nematodes of cereals are cereal cyst nematode (cereal root eelworm) of the winter cereals and the root lesion nematodes of wheat.

Seed-Borne Diseases

Some diseases such as the loose smuts of winter cereals and barley stripe are exclusively seed-borne. In the case of loose smut, infections occur at flowering and the mycelia are actually present within the seed tissue and the pathogens develop with growth of the host. The primary means of dispersal for many pathogens is with seed, either as, or on, contaminating material, present on seed surfaces or in infected seed that may or may not be viable. These pathogens are then available to infect germinating seedlings to produce seedling blights, or to induce stress symptoms at later growth stages. Alternatively, fungal pathogens present on the soil surface may produce conidia that can be splash-dispersed to above ground tissues. Some bacterial and virus pathogens are also seed-borne.

Residue-Borne Diseases

This group is probably the largest and most important group of pathogens of cereals and their significance has greatly increased in large-scale agriculture with its increased monoculture and minimum tillage, or no-tillage, practices where residue is retained on the soil surface to prevent soil erosion. Fungal pathogens of this type survive from season to season as mycelium and resting structures on host debris. While deep-plowing and burning can give marked reductions in levels of many of these diseases, such practices are not encouraged, especially where soil surfaces remain vulnerable to erosion.

Diseases in this group often infect young seedlings, giving rise to early damping off or wilting symptoms (e.g., *Fusarium* blights) or may remain in the root, subcrown, and crown regions to develop disease symptoms at later growth stages, especially at times of short-term or long-term moisture stress. In the winter cereals, these symptoms result in premature death, wilting, "white heads," and lodging. Examples of such diseases include common root rot, eyespot and crown rot of wheat. Wheat crown rot is caused by

Table 1 Major diseases of cereal grain crops, causative agents, means of infection, spread, survival, pathogenic variability, and host range

Crop	*Disease name and pathogen type*[a]		*Pathogen: anamorph (teleomorph)*	*Disease type*[b]	*Means of infection*	*Path var*[c]	*Methods of control*	*Overseason survival*	*Infection of other cereal crops*
Wheat and durum	Take-all, firing	F	*Gaeumannomyces graminis* var. *tritici*	Soil-borne	Mycelial penetration of roots and crown	1	Crop rotation, take-all decline	Volunteer cereals and grasses, residues	Barley, triticale, rye
	Cereal cyst nematode	N	*Heterodera avenae*	Soil-borne	Penetration of roots	3	Nematicides, crop rotation, resistance	In soil	Barley, oats, triticale, rye
	Root lesion nematode	N	*Pratylenchus* spp.	Soil-borne	Parasite of roots	1	Crop rotation, some resistance	In soil, other host species	No
	Crown rot	F	*Fusarium pseudo-graminearum, F. culmorum, Fusarium* spp.	Residue-borne	Stem base and subcrown internode	1	Rotation, stubble management, partial resistance	Crop residues	Barley, triticale, oats (symptomless)

Barley	Cereal cyst nematode	N		Soil-borne	Penetration of roots	3	Nematocides, resistance	In soil	Wheat, oats, triticale
	Common root rot, Spot blotch	F	*Bipolaris sorokiniana (Cochliobolus sativus)*	Seed- and residue-borne	All tissues by conidia	1	Seed dressings, rotation, stubble management, resistance	Crop residues	Wheat, triticale
	Crown rot	F	*Fusarium pseudo-graminearum, F. culmorum, Fusarium* spp.	Residue-borne	Stem base and subcrown internode	1	Rotation, stubble management, partial resistance	Crop residues	Wheat, triticale, oats (symptomless)
	Net blotch – net form	F	*Drechslera teres* f. *teres (Pyrenophora teres)*	Seed-, residue-, and soil-borne	Wind and splash dispersed conidia, and ascospores	1	Seed dressings, stubble management, resistance	Residues	No, wild *Hordeum* spp.
	Net blotch – spot form		*D. teres* f. *maculata (Pyrenophora teres)*	Seed-, residue-, and soil-borne	Wind and splash dispersed conidia and ascospores	1	Seed dressings, stubble management, resistance	Residues	No, wild *Hordeum* spp.
	Scald	F	*Rynchosporium secalis*	Seed- and residue-borne	Splash dispersed conidia	2–3	Seed dressings, stubble management, resistance	Green-bridge, residues	No, wild *Hordeum* spp.
	Barley stripe	F	*Helminthosporium graminum (Pyrenophora graminea)*	Seed-borne	Systemic infection of seedlings	2–3	Disease-free seed, seed dressings, resistance	Seed	No
	Fusarium head scab	F	*Fusarium graminearum, (Gibberella zeae), F. culmorum, Fusarium* spp.	Trash- and seed-borne	At anthesis by splash-borne conidia or ascospores	2	Stubble management	Crop residues, other species?	Barley, triticale, corn, others, saprophyte on rice residues
	Stem (black) rust	F	*Puccinia graminis* f. sp. *tritici*	Airborne	Uredospores	4	Foliar sprays, resistance	Green-bridge	Wheat, triticale
	Leaf (brown) rust	F	*P. hordei*	Airborne	Uredospores	4	Foliar sprays, resistance	Green-bridge	No

	Stripe (yellow) rust	F	*P. striiformis* f. sp. *hordei*	Airborne	Uredospores	4	Foliar sprays, resistance	Green-bridge	No, wild *Hordeum* spp.
	Barley yellow dwarf	V		Vector-borne	Several aphid spp.	2	Control of aphids, partial resistance	Green-bridge for aphids	Other cereals, grasses
	Powdery mildew	F	*Blumeria graminis* f. sp. *hordei*	Airborne ascospores and conidia	Leaf	4	Foliar sprays, resistance	Cleistothecia on residues, green-bridge	No
	Barley stripe mosaic	V		Seed-borne	Infected seed, mechanical transmission	1	Virus-free seed	Infected seed	Wheat, oats, grasses
Oats	Cereal cyst nematode	N	*Heterodera avenae*	Soil-borne	Penetration of roots	3	Nematocides, crop rotation, resistance	In soil	Barley, oats, triticale
	Stem (black) rust	F	*Puccinia graminis* f. sp. *avenae*	Airborne uredospores	Leaf, stem, and inflorescence	4	Resistance	Green-bridge	No, wild oats important
	Leaf (crown) rust	F	*Puccinia coronata* f. sp. *avenae*	Airborne uredospores	Leaf	4	Resistance (extremely ephemeral)	Green-bridge	No, wild oats important
	Barley yellow dwarf	V		Vector-borne	Several aphid spp.	2	Control of aphids, partial resistance	Green-bridge for aphids	Other cereals, grasses
	Powdery mildew	F	*Blumeria graminis* f. sp. *avenae*	Airborne ascospores and conidia	Leaf	4	Foliar sprays, resistance	Cleistothecia on residue, green-bridge	No, wild oats
Cereal rye	Ergot	F	*Claviceps purpurea*	Seed- and soil-borne	Flowers	1	Control of grass weeds	Sclerotia in soil or seed lots	Other winter cereals and grasses
	Stem (black) rust	F	*Puccinia graminis* f. sp. *secalis*	Airborne uredospores	Leaf, stem, and spike	4	Resistance	Green-bridge	No, some grasses
	Leaf (brown) rust	F	*Puccinia recondita* f. sp. *recondita*	Airborne uredospores	Leaf, stem, and spike	4	Resistance	Green-bridge	No, some grasses
Corn	*Gibberella* stalk and ear rot	F	*Fusarium graminearum*, (*Gibberella zeae*), *Fusarium* spp.	Seed- and trash-borne	All growth stages by ascospores and conidia	1	Stubble management, crop rotation, resistance	Perithecia and hyphal structures in residue and seed	Wheat, barley, grasses, possibly other crops
	Diplodia stalk and ear rot	F	*Diplodia maydis*	Seed- and trash-borne	Seedlings and nodal regions by pycnidiospores	1	Stubble management, crop rotation, resistance	Pycnia on seed and residues	No
	Fusarium stalk and ear rot	F	*Fusarium venticillioides*	Seed- and trash-borne	Hyphal infections of most tissues	1	Measures to reduce stress	Hyphae in seed, hyphae and conidia in residues	Can affect sorghum and millet
	Northern leaf blight	F	*Helminthosporium turcicum*	Splash-borne	Conidial infection of leaves	2	Stubble management, crop rotation, resistance	Possibly conidial structures on residues	Sorghum, some related grasses
	Southern leaf blight	F	*Helminthosporium maydis*	Splash-borne	Conidial infection of all tissues	2	Resistance, especially avoidance of T-cytoplasm	Conidia on residues	No
Sorghum	*Fusarium* stalk rot	F	*Fusarium thapsicum*	Seed- and residue-borne	Hyphal infections of most tissues	1	Measures to reduce stress	Hyphae in seed, hyphae and conidia in residues	Primarily grain sorghum

	Hoja blanco	V		Vector-borne	*Sogatodes orizicale*		Resistance	Green-bridge	No (Central and South America)

[a] Pathogens: F = fungal, N = nematode, V = virus, B = bacteria.
[b] "Residue" refers to partially decomposed material either on the surface or within the soil. Residues may carry saprophytic fungal mycelia or resting structures.
[c] Pathogenic variability: 1 = no significant variability to 4 = high degree of variability.

Fusarium spp. It is of interest that the *Fusarium* head blight pathogen, *Gibberella zeae*, is not a significant cause of crown rot although it can produce seedling wilt. Crown rot of wheat and barley is caused by *F. pseudograminearum* in warmer areas and by *F. culmorum* and other species in cooler areas. Other members of this group of pathogens are dispersed as conidia or ascospores by raindrops or wind to infect leaf tissues or even inflorescences. They include most of the fungal leaf spot, blotch and streak pathogens and their spread within the canopy is dependant on periods of consistent light rainfall. These diseases are often present but not damaging. However, when environmental conditions are optimal they can be very damaging with total loss of green leaf tissue and subsequent grain losses of up to, and sometimes exceeding, 50%. Many of these diseases are cyclical in occurrence involving combinations of susceptible host genotypes and sequences of years of favorable conditions during which there is a gradual increase in inoculum loads. Examples include the southern corn leaf blight epidemic in the USA in 1969–70 and the wheat yellow leaf spot epidemic in eastern Australia in 1998. The corn leaf blight epidemic involved susceptible corn hybrids based on T-cytoplasm and disease occurrence and risk was reduced by a return to normal cytoplasm and mechanical detassling of female parents for hybrids. The yellow leaf spot problem in Australia declined with less favorable environmental conditions and release and recommendations of less susceptible cultivars. Sporadic epidemics seem to be associated with sequences of unusually favorable seasons combined with a suite of susceptible cultivars that are approved during the intervening periods.

The most damaging diseases of this group are eventually those that progress to the inflorescence or involve the inflorescence. Examples include *Septoria nodorum* blotch of wheat and *Fusarium* head scab (FHB) of wheat and barley. FHB is caused by *G. zeae* in high temperature areas with wheat: maize rotations (e.g., mid-western and eastern USA, central and southern Europe) and wheat : rice rotations (e.g., in the Yangtze valley in China), by *F. culmorum* at moderate temperatures and by *Microdochium nivale* at lower temperatures. *G. zeae* also causes stalk rot and pink ear rot of corn. On the other hand, *G. zeae* is not a common pathogen of rice; the fungus behaves as a saprophyte on rice stubble (and probably sorghum), thus maintaining high inoculum levels for subsequent wheat crops. Barley, especially two-row genotypes, is less susceptible to FHB than wheat suggesting the rate of spread is influenced by spike structure. Blast, probably the most important fungal disease of rice, spreads by splash-borne conidia. The blast pathogen also

causes grey leaf spot of turf grasses (perennial ryegrass) and has recently become a pathogen of wheat in Brazil. However, the isolates from grasses are nonpathogenic on rice and the form attacking wheat is more closely related to those attacking grasses than isolates from rice. Despite a teleomorph stage (*Magnaporthe grisea*), dispersal of blast in nature is exclusively by conidia. Under extreme conditions when infections by splash-borne organisms reach the upper canopy, their epidemiological dynamics may change to become more like air-borne diseases typified by long distance spore dispersal.

Airborne Diseases

This group includes the rusts of all major cereals except rice and the powdery mildews of wheat, barley, and oats. The rusts are among the main diseases affecting oats and wheat with powdery mildew being more important on barley. Both the rusts and powdery mildew pathogens (as well as some splash-borne pathogens such as the rice blast pathogen) are highly variable and occur as *formae speciales* or specialized taxonomic varieties on individual species as well as pathotypes or pathogenic races within those groups.

Most of the rusts are heteroecious species with the telial stages occurring on cereals and the aecial stages on other (dicotyledonous) species. The rust pathogens cannot survive for long periods away from a living host, although they can survive as uredial infections in most areas provided a "green-bridge" is available. This green-bridge includes self-sown or regrowth plants from earlier crops or along transport corridors (roads, railway lines, storage sites) and a restricted range of "accessory" grass hosts that varies for each pathogen. In addition, uredospores can be transported over long distances by wind as documented by studies in North America and Australia. In certain rusts and in some locations where the aecial stage contributes to overall epidemiology (note the stripe rust pathogens have no known aecial stage), the black telia that develop on maturing host leaf and stem tissues provide a resting stage for overwintering. In early spring, the teliospores from within the telia germinate, and undergo meiosis to form basidiospores that infect the new spring growth of the alternate hosts and form pycnia. There, the different mating types undergo fertilization to produce a dikaryotic aecium and aeciospores reinfect the grass host species. This cycle, when it occurs, has two main effects on epidemiology. First, it provides a mechanism for survival and early infections in areas where uredial survival is prevented by cold winters and second, meiosis allows reassortment of the genotype providing an efficient means of creating new pathotypes. Despite an absence of alternate hosts in many cereal-growing areas the rust pathogens, including *P. striiformis*, are nevertheless highly variable, with mutation and somatic hybridization (asexual recombination) the likely mechanisms.

The powdery mildew pathogens are ascomycetes. Survival between seasons is by green-bridging and by cleistothecia that develop on ripening host tissues and survive on the debris. Karyogamy and meiosis occur in the cleistothecia and the released ascospores infect young cereal plants on which the organisms recycle as conidia. Again, meiosis allows for genetic assortment, but the powdery mildew fungi and the blast pathogen are monoploid (n) organisms in contrast to the rust pathogens that are dikaryons ($n+n$) and functionally similar to diploids ($2n$).

Vector-Borne Diseases

This group includes the many virus diseases that affect cereals in different locations. However, relatively few virus diseases of cereals are significant on a worldwide basis. Tungro of rice and barley yellow dwarf (BYD), cereal yellow dwarf (CYD) and wheat streak mosaic on small grain winter cereals are among the most important. Viruses are transmitted from plant to plant by vectors that include insects, particularly aphids and leaf-hoppers, mites, and fungi. Knowledge of the biology and migratory behavior of vectors, and of specific virus strain: vector relationships, is essential to understanding the epidemiology of virus diseases and to the development of control strategies. In addition, some viruses can transmit between neighboring plants through contact of injured tissues.

BYD can be caused by one or more of several luteoviruses spread by a range of cereal aphid species, hosted by a number of grasses including corn. This complex of variable viruses, aphid species, host species (cereals, pasture species, native grasses), and environments adds to the problems of managing this disease, especially in mixed farming areas. WSM, vectored by the aerially dispersed wheat curl mite *Aceria tulipae,* and infecting a range of cereals and grasses that host the mite, is responsible for significant losses in wheat and barley in North America, eastern Europe and the Near East. Autumn or early winter infections of BYD, CYD, and WSM in winter cereals or autumn-sown spring cereals can result in very significant yield reductions; spring infections when plants are more developed lead to lower losses.

Diseases of the Inflorescence, Spike, and Seed

These diseases are the most important for commerce. They include the black point/kernel smudge complex

already discussed, the smuts, leaf diseases that also affect the spike and glumes, head scab and ear rots, and also the non or weakly pathogenic molds and rots. There are two aspects: firstly the effects of seed-borne diseases on the seed industry, and secondly, the effects on trade and endpoint use. The smuts destroy the inflorescence and thereby reduce yields. Some smuts such as common bunt and karnal bunt of wheat produce unpleasant odors and flavors. The scab and cob rots, especially those caused by *Fusarium* spp., may carry a variable complex of compounds (including vomitoxin = deoxynivalanol (DON), nivalanol (NIV), and related trichothecenes) that are toxic to man and animals. In the various fungal species, these compounds appear to act as virulence factors, enhancing the ability of the pathogens to colonize the hosts. The particular compounds and their amounts not only vary among the species but also between isolates within species. In addition, there are various molds and rots of stored grains caused by a range of weakly pathogenic and nonpathogenic fungi that come into contact with the grain during ripening and harvesting. These tend to be associated with grain, ripened or harvested under wet conditions or harvested at high moisture content. Shriveled seed harvested from crops with a range of diseases may have qualities that differ from grain harvested under optimal conditions.

Plant Quarantine Issues

Countries vary in regulations that apply to imported seed for either propagation or commerce. Plant pathogens can be carried either as infections within the seeds (certain smuts, seed-borne viruses), as contaminants on the seed surface (many bacteria and fungi), or on plant debris or soil that may be present as admixtures with grain. To reduce risks, preborder measures such as local import permits and phytosanitary certificates issued by the originating country may be required. On arrival in a receiving country, seed for propagation may be inspected before being grown in quarantine greenhouses or approved isolated field areas. Grain in large quantities for commerce may require special treatments to kill the embryos or may be milled in approved locations away from local cereal production areas.

With the recent large-scale rapid movement of goods and people around the globe even nonseed-borne pathogens can move over large distances as contaminants of traded goods or persons. For example, following the introduction of the wheat stripe pathogen into eastern Australia, probably from Europe, in 1979, there have been at least two further incursions. In 1998, a *Puccinia striiformis* form more adapted to barley grass (*Hordeum leporinum, H. murinum*), than to wheat or barley was observed for the first time, and in 2002, a distinct pathotype of *P. striiformis* f. sp. *tritici* appeared in Western Australia, which previously had been free of stripe rust. The origins of these new forms have not been established. They are assumed to have arrived on contaminated clothing or footwear.

The Hazards of Chemical Control

Many diseases, or the vectors that transmit pathogens, especially viruses, can be controlled effectively with chemicals applied as seed dressings or as foliar sprays at appropriate growth stages. In high-yielding environments, one or more chemical applications are often included as part of a routine management package. Under these circumstances, favorable returns can be achieved even where disease levels appear to be low. As environments become less favorable and yield levels decline, or for lower value grains for fodder, the costs of chemical applications encroach on profitability to the extent that their use on crops with yield potentials below $2-3\,\mathrm{t\,ha^{-1}}$ may be uneconomic. This is a very significant factor of production in major exporting countries such as Australia and Canada with relatively low-average long-term wheat yields, for example, of 1.7 and $2.3\,\mathrm{t\,ha^{-1}}$, respectively. Under these production systems, agronomic and genetic means of disease control are more attractive.

A further major consideration is the increasing emphasis on quality standards and declining chemical residue limits placed on traded grain and grain products. Presumably, the later in growth that a chemical is applied, the greater the likelihood of residues exceeding specified limits, leading to down-grading or blending of grain to achieve specified standards.

Control of Diseases by Plant Breeding

Many of the diseases of cereal crops have and continue to be controlled by resistant genotypes. Resistance has the advantage of being residue-free and of contributing to lower production costs for the farmer. No cultivar of any crop has resistance to all disease threats nor provides complete resistance under all conditions. Hence, chemicals to target single diseases, or to provide prophylactic protection to a range of threats, are often used, especially under high-yielding conditions. A recurrent problem with resistance has been the emergence of resistance-breaking pathotypes as a result of selection of previously infrequent variants, sexual and/or nonsexual recombination in nonhaploid pathogens, and mutation. Retrospective

genetic analyses of hosts and pathogens in situations where both resistant and susceptible host genotypes, and both avirulent and virulent pathogen genotypes were available showed that expression of resistance is dependent upon the presence of a corresponding gene for avirulence, a gene-for-gene relationship. Assumptions of a gene-for-gene relationship in disease systems where genetic information is lacking permits postulation of resistance and avirulence genotypes (phenotypes) and thereby assists the breeding of resistant cultivars based on gene combinations. However, major gene combinations have usually not provided long-term solutions and breeders have had to continue the search for even more resistance genes, or to seek alternative breeding and deployment strategies. These include genotype (and crop) mixtures, minor resistance gene combinations, and various partial resistances with a history of durable resistance. Nevertheless, some resistances, represented by single genes (*mlo* for powdery mildew resistance in barley, *Sr2* for stem rust resistance in wheat) or by more complex resistance sources (flagsmut resistance in wheat), have remained effective over long periods. Resistance to some diseases (e.g., take-all of wheat) does not exist and to others (e.g., crown rot of wheat and barley) only relatively low levels of partial resistance (or tolerance) are available. Nevertheless, such variability can be used very effectively in integrated disease control to improve farm profitability.

Future Prospects

Cereal crops will continue to be affected by diseases as no breeding program can develop cultivars with acceptable levels of resistance to all diseases under all conditions. Emphasis on resistance is expected to increase as fungicide use and residues become less acceptable. Molecular biology is providing tools for more accurate diagnostics of pathogens at both species and subspecies levels, some pathogenicity factors have been cloned and their gene products identified. In the host species, resistance genes have been mapped and cloned. Mapping information is being used for marker-assisted selection, aimed at developing resistance gene combinations to provide more durable and effective resistances. Genetic transformation will provide opportunities for transferring resistance genes from species that cannot be hybridized with individual cereal species as well as possibilities for synthesizing new genes in the laboratory. Genetic engineering seems likely to provide resistance to diseases for which adequate and effective resistance is currently not available.

Grain – Quality Attributes

C F Morris, Western Wheat Quality Laboratory, Pullman, WA, USA

Published by Elsevier Ltd.

Why Is the Quality of Cereals Analyzed?

Because cereal grains (and the products derived from them) are biological entities and can vary dramatically. Further, the ways in which different samples of the same cereal grain vary can have a profound impact on processing, nutrition, and consumer appeal.

So, if it is important to analyze quality, what is "quality"?

Quality in this context is "the degree or grade of excellence." Quality may also be thought of as *suitability*. Consequently, to understand the analysis of cereal quality, one must appreciate the array of end uses of the various cereals. The major cereals and their uses are presented in Table 1. The organization of this chapter follows this general scheme. Feed uses of all cereals are discussed separately. First, some general considerations.

General Considerations

The success of cereals as food and feed crops stems from the ability to store easily the grain produced from them for a long period of time. Compare this feature to fruits, vegetables, and meats. Add to this the productivity and broad adaption of most cereal crops, and their relatively high nutritive characteristics, and it is clear why cereals play a prominent, central role in agriculture. This article covers the analysis of quality of the major cereal crops. Their prominence is evidenced by their production: ~590 mmt (million metric tonnes) annually for wheat, 400 mmt for rice (milled), 590 mmt for maize, 140 mmt for barley, 51 mmt sorghum, 25 mmt for the millets, 26 mmt for oats, 20 mmt for rye, and 10 mmt for triticale.

Cereal quality can be considered at two levels: (1) characteristics of grain lots or samples, and (2) the intrinsic quality of the grain itself which results from an interplay of genetics and the weather, management, postharvest storage, pathogens, insects, etc. The first of these characteristics of grain lots includes not only the intrinsic quality of the cereal grains themselves, but such things as the presence of seeds of other species, seeds of different types of the same species (e.g., soft red wheat contamination in hard white wheat), presence of dirt, stones, chaff, animal filth, or insects. This article assumes that a given lot of grain has been cleaned and is free of these sorts of contaminants. However, in practice, the complete removal of some of these factors is either physically impossible or economically impractical. Consequently, standards for inspecting and grading grain often severely penalize these factors. The second level of quality consideration is at the intrinsic level. As mentioned above, all intrinsic properties result from the interplay of the genetic makeup of the plant and the way in which it interacts with (or responds to) external factors. Some external factors exert a very dramatic effect on quality and the range of effects may be an order of magnitude greater than that observed among a group of varieties. In the other extreme, the expression of some quality genes is essentially minimally affected by external influences such that variation among grain lots is essentially controlled by differences in genes. Between these two extremes is a full range of quality traits that have greater or lesser degrees of genetic versus environmental influence. Table 2 lists a few examples of quality traits that are variously affected by external factors.

Since all of the cereal grains are botanically related, and all of the grains are technically caryopses, some general description of cereal grains can be made. All cereal grains are composed primarily of an endosperm attached to a germ (embryo) via a scutellum, and enclosed in several layers of tissues collectively referred to as the bran. These three different parts have quite different biological roles, and hence quite different compositions and structures. Because of these differences, humans utilize each in markedly different ways. Additionally, rice and most barley and

Table 1 Major cereals and their uses

Common name	*Genus and species*	*Major uses*
Wheat		
Bread wheat	*Triticum aestivum* L.	Many styles of pan breads, hearth breads, noodles, starch and gluten, animal feed

Frost damage		

oat varieties are also enclosed in adhering lemma and palea when harvested. These are removed during their processing for human food.

The endosperm is the key feature of cereal grains. For the cereal crops of significance, most have endosperms comprised of starch (60–75%), protein (6–19%), fiber (3–8%), and oil (1–4%). As opposed to most grain legumes, tree nuts, and horticultural crops, cereal crops store most of the energy for germination and seedling emergence in the form of starch. Nitrogen reserves are deposited in the grain in the form of protein "bodies" and "matrix" protein, which surrounds the starch granules and protein bodies.

Cereal germs are relatively rich in oil. In the case of wheat, millers desire to remove the germ because its oil contributes to rancidity of flour. In maize, the germ contributes to the feeding value (energy) of whole grain and is the source of food oil in the milling process.

The bran and husk (lemma and palea) are of little direct value since they are largely cellulose and are undigestible by humans and most livestock. However, the husk is an important part of the filtration process in brewing with barley malt, and can protect the seed – especially the germ – from mechanical damage during harvest.

Wheat

The analysis of the quality of wheat is by far the most complex of all the cereal grains. This complexity reflects the tremendous diversity of the genetics of wheat, the tremendous diversity of the uses of wheat, and the central role that wheat plays in the human diet. Wheat has distinguished itself from all other cereals and grain legumes because of the unique properties of its endosperm storage proteins. These proteins, classified as glutenins and gliadins, when hydrated and mixed (by hand or machine) form "gluten." Gluten is unique in that it exhibits both viscous and elastic properties. These properties allow gluten to form a continuous membrane which can retain the gases produced in fermenting doughs. The retention of these gases greatly decreases the density of doughs, and upon baking, this light, airy structure is fixed.

An almost limitless number of foods are made from wheat. Wheat flour, bran, etc., are also important food ingredients. Table 1 lists the major uses of wheat and flour. The quality of a particular flour is not necessarily low or high until it is judged in the context of a particular end use. For example, a flour that exhibits very high bread baking quality generally also has very poor cookie or cake baking quality. Therefore, wheat quality is defined by an almost infinite number of different food products which contain flour, starch, gluten, bran, whole and cracked grain, etc.

The majority of wheat is first milled into flour, and consequently the miller is in a central and critical position in the utilization of wheat as a food. The miller takes a raw material of biological origin and converts it into a food ingredient for countless numbers of diverse food products. Much of the day-to-day success of the baker is a direct result of the miller's technical ability and expertise. In this regard, the overriding aspect of flour quality is consistency of performance. This endeavor is by no means simple or straightforward. Wheat is a biological entity and as such can vary dramatically over geographical locations, over years and importantly, among different cultivars. In one sense it is the miller's task to remove this variation and thereby produce a consistent product. Flour milling is more extensively presented in **Wheat**: Dry Milling.

The various categories of wheat foods described in this article include pan, hearth and other fermented (leavened) breads, steamed breads, flat breads and crackers, cookies, cakes, and other soft wheat products, noodles, breakfast foods, and pasta and durum wheat products.

Fermented (Leavened) Breads

Leavened breads include traditional white pan, variety, hearth and sourdough breads, sweet goods including yeast-leavened doughnuts, and bagels. Rolls are simply smaller-sized products and may be similar to other, larger breads and sweet goods. Leavened breads are characterized by a crumb texture that is light, airy, and porous, yet chewy. One of the primary determinants of this texture is the quantity and quality of gluten protein.

By far the most common type of leavened bread in the West is white pan bread made from straight-grade or patent flours of hard spring and winter wheats. White pan breads require high flour water absorption, medium to strong dough mixing strength, extensible gluten, and good fermentation and mixing tolerances. Large loaf volume and fine, smooth crumb grain are desirable. A smaller version of pan bread is the sandwich bun. McDonald's alone sells over 8 billion sandwich buns per year worldwide, nearly 5 billion in the US. The US portion of sales consumes nearly 200 million kg of flour – ~1% of all the flour produced in the US. Variety breads are embellished versions of white pan. These breads are prepared using whole-wheat flour and/or as many as a dozen different ancillary ingredients.

Hearth breads were the forerunners of pan breads. Hearth breads are baked on the oven floor, or sole. As a consequence, they range from having an ovate or nearly spherical shape to one approximating a horizontal cylinder. In addition to affecting the shape, the absence of baking pans exposes the entire bread surface to the oven environment. This large, exposed surface area produces the greater crust-to-crumb ratio characteristic of hearth breads. Perhaps the most famous hearth bread is the French baguette. Many hearth breads are characterized by long fermentation and no antistaling additives.

Sourdough bread is similar to white hearth bread except for its characteristic sour, acidic flavor, and extra-chewy texture. Sweet goods, on the other hand, are characterized by rich formulas high in fat and sugar and contain milk solids and eggs. These products are more varied but generally require flours similar to other leavened breads. Products include yeasted doughnuts, cinnamon rolls, coffee cakes, Danish and puff pastries, and French brioche.

Doughnuts are of two general types: yeast leavened and cake. The unique characteristics of doughnuts is their traditional ring shape and the method of frying in hot oil. Yeast-leavened doughnuts are similar to bread in that they are made from yeast-fermented doughs.

Bagels are doughnut-shaped rolls. The word bagel comes from the Austrian–German word *bugel*, meaning stirrup. Bagels were invented over 300 years ago to honor Jan Sobieski, king of Poland and famed equestrian. Bagel doughs are retarded for up to 20 h and then boiled just prior to baking. A traditional style of bagels requires very chewy texture.

Steamed Breads

Asian steamed breads are simply breads that are steamed rather than baked. As such, they lack the brown crust that is characteristic of oven-baked breads. They may be plain or with a sweet bean paste or savory meat filling. Steamed breads are traditional wheat foods in China, Japan, The Philippines, and other East Asian countries. Two main types are consumed in China: northern style and southern style. Northern style is larger and chewier, and is made from the higher-protein, stronger-gluten wheats of that

region. Southern style is smaller, of lower density, and often sweeter.

Flat Breads and Crackers

Flat breads and crackers are usually no more than 6 cm and often less than 3 cm thick. Most flat breads are higher in water content than crackers, and are therefore chewy as opposed to crisp. Most crackers have no discernable crumb and crust. The majority of flat breads are consumed in North Africa, the Middle East, and the Indian subcontinent. Major types include “chapati,” “roti,” “naan,” “paratha,” “poori,” “balady,” “pita,” and “barabri.” These breads typically have high crust-to-crumb ratios and limited crumb. They are generally baked at very high temperatures for very short time periods (e.g., 550°C for 30 s). Flat breads are typically produced from high extraction (75–90%) or whole wheat flours. Due to the higher bran content of these flours, white wheat is preferred for lighter color. Much less gluten strength is required compared to pan and hearth breads for two reasons: (1) the limited crumb does not require much gas-holding capacity, and (2) many of these breads are prepared by hand and weaker gluten is easier to mix and handle. Due to their geometry and structure, tortillas, pizza crust, English muffins, crumpets, and pretzels can be considered flat breads. Tortillas, which are traditionally made from maize, are flat breads indigenous to Mexico, Central America, and the southwestern US.

Pretzels are unique because they receive an intermediate processing step. Two types of pretzels are popular. The first tend to be small (~10 cm), and may be in the characteristic twisted shape or other configurations such as short, straight sticks or rings. These products are baked and then dried to ~2–3% moisture content and have a crunchy texture and a relatively long shelf life. The second type, soft pretzels, tend to be much larger, up to 30 cm with the baked dough piece diameter ~2–4 cm. Moisture content is higher and the texture resembles chewy bread. In addition to the characteristic twisted shape, the feature that sets pretzels apart is the use of caustic lye (usually 1.25% NaOH). The dough pieces are immersed briefly in hot lye solution, baked, and then sprinkled with coarse granular salt.

Pizza crusts in the US are typically made from higher-protein, stronger-gluten flours. English muffins and crumpets are flat breads characterized by a coarse, open grain, grilled top and bottom with light sides, and a flat disk geometry.

Crackers are characterized by thin geometry, low water content, and crisp, crunchy texture. Crackers are popular in North America, Europe, and Australia. Products include soda crackers, cream crackers, water biscuits, graham crackers, sprayed crackers, and savory crackers. Soda crackers, or saltines, are the most definitive cracker product. They are prepared by fermenting a relatively stiff, dry dough. Fermentation is partially accomplished by lactic-acid-producing bacteria. Sodium bicarbonate (hence the name soda cracker) is added to neutralize the drop in pH.

Cookies, Cakes, and Other Soft Wheat Products

Soft wheat is used in many diverse food products. In some it is the major ingredient, but in others it ranks second or third. Soft wheat is used in these applications, because (1) the stronger gluten and higher protein levels of hard wheat reduce product quality, (2) soft wheat flours have lower levels of starch damage and consequently lower water absorption and dough viscosity, (3) soft wheat flours generally have a finer texture, or smaller particle-size distribution, and (4) soft wheat is often cheaper than hard wheat and thus reduces ingredient costs. Often a blend of the two types provides an intermediate level of gluten strength. As opposed to hard wheat flour, where the inherent strong viscoelasticity of gluten is the primary reason for its use, soft wheat flour usually has weak, extensible gluten. This lower strength of gluten translates into soft, tender texture of soft wheat products. The major food uses of soft wheat flour are chemically leavened crackers, pie crust, cookies (biscuits), American-style biscuits, scones, Moon Cake, products made from batters (sugar wafer cookies, ice cream cones, pancakes, and waffles), cakes, tempura, breadings, and soup thickeners.

Chemically leavened crackers are similar to fermented crackers except for their method of leavening, which is usually sodium bicarbonate with an acidifying salt. Pie crust has a high fat content and little structure; it is usually sheeted.

Cookies (biscuits) generally have limited three-dimensional structure, a high content of sugar and fat, and generally a low moisture content. Most are chemically leavened to reduce product density and impart a desirable texture. The major types of cookies (from lowest to highest water content) are rotary molded, cutting machine, wire-cut, and deposit varieties. In the UK and its former colonies, chemically leavened cookie doughs are classified as short-dough sweet biscuits (sweet biscuits, short doughs, or short sweet doughs) and hard-dough semisweet biscuits. “Marie” and “Rich Tea” are popular examples of hard-dough semisweet biscuits. In these products, gluten is partially developed. Short-dough sweet biscuits may be classified according to the US system.

In rotary-molded cookies the dough is pushed into dies cut on the surface of a smooth cylinder, excess dough is scraped off, and the cookie is released onto a canvas conveyor and moved to the oven. The dies produce three-dimensional raised designs which are maintained after baking. Often, a cream filling is deposited between two cookies (i.e., "sandwich" cookies). Cutting machine cookies are produced from a sheeted dough. Various shapes are cut from the dough sheet and baked. The wire-cut cookie is the most common commercial cookie in the US. A popular variation includes chocolate chips. Wire-cut cookies are produced by passing a taught wire through a stream of extruded dough. Individual dough pieces drop onto a belt and are conveyed to the oven. Deposit cookies are made from higher moisture doughs, some approaching the viscosity of cake batters. Deposit cookies are produced by extruding the dough through nozzles where reciprocating cutters release the dough onto the conveyor, or oven band. Popular variations are the vanilla wafer and Danish butter cookie.

Batter products include some low-moisture, crisp products such as wafer cookies and ice cream cones; griddle cakes such as pancakes and waffles; a vast array of higher volume cakes; and coatings such as tempura. Pancakes are relatively thin, round cakes prepared by cooking batter on a hot griddle or pan. Oil on the griddle surface fries the outer surface of the pancake to a golden brown. Waffles are prepared from similar batters but are cooked in a two-sided griddle which imparts the characteristic three-dimensional structure and crisp texture. Where pancakes are fried in a thin layer of oil, doughnuts are completely immersed in hot cooking oil. Cake doughnuts, in contrast to yeast-leavened doughnuts, are made from a formula similar to a standard layer cake which uses both chemical leavening and incorporated air to obtain the desired low product density.

Cakes are baked foams and usually have substantially higher proportions of fat and sugar compared to breads. Cakes derive their light, porous texture through the use of leavening agents such as sodium bicarbonate and/or through the entrapment of minute air bubbles. Like cookies, cakes exhibit little gluten development; gluten development is detrimental to cake quality and imparts an undesirable tough chewy texture. In contrast to cookies that have generally less than 2–3% moisture, cakes are formulated to produce tender, moist textures. Cakes, depending on type, may have amounts of sugar, eggs, and fat in their formula which exceed the quantity of flour. In high-ratio cakes, as the name implies, sugar-to-flour ratios may range from 1 to as high as 1.2. In the case of angel food cake, sugar and egg whites may each exceed flour by a ratio of 2.75. Cakes are made from batters with substantially lower viscosity than cookies or bread doughs. Consequently, the stable entrapment of minute air cells is critical to cake volume and texture. The formation of emulsions with formula fat or egg lipids is crucial for the entrapment of air bubbles and for preventing the establishment of a continuous gluten network. In many cakes, the structure-forming role of egg white or whole egg protein is important. Cakes are often highly flavored with high proportions of chocolate, fruit, and other ingredients. Some of the main classifications of cakes are high-ratio, pound, chocolate, yellow and white layer, sponge, Swiss roll, chiffon, angel food, cup cakes and muffins, and Japanese *castilla* varieties.

Tempura is a Japanese batter used to coat seafood and vegetables prior to deep-fat frying. Breadings, like tempura, are used to coat foods and often to impart a crunchy texture. Soup thickeners are used to provide a high viscosity to soups. Therefore, starch plays the most important role and flours must be free of amylases associated with preharvest sprouting.

Noodles

In this article, differentiation is made between *noodles* prepared from common, or hexaploid, wheat flour, and *pasta* prepared from durum semolina. Noodles may be generally defined as boiled "strings" of unleavened wheat dough. However, this definition has many exceptions and caveats due to the tremendous diversity of noodle products. Most noodles are produced and consumed in eastern Asia, and as such, their use runs parallel to bread consumption in the West. Noodles are the traditional form in which wheat is consumed and predates recorded history. In addition to rice, noodles form the foundation of the carbohydrate-based diets in that part of the world.

Although tremendously diverse, the vast majority of noodles are prepared from very simple formulas: flour, water, and salts. Because of this, wheat flour quality is particularly critical in determining noodle quality and consumer acceptance. For the purposes of classification and discussion, noodles may be grouped according to formulation (primarily type of salts), noodle geometry, method of preparation, postpreparation processing, method of packaging, and manner in which they are consumed.

Based on formulation, noodles may be classified as white salted, alkaline, "soba," or egg. Additionally, ramen or instant noodles are noteworthy. A number of noodle-like sheeted products include egg roll, pot sticker, and won ton wraps.

The three main features of white salted noodle quality are color, appearance, and texture. Noodle color should be clear and bright, not dull or dark. The leading factor in good color is the absence of discoloring enzymes called polyphenol oxidases. The noodle should appear smooth with a glossy surface and should have square, well-defined edges rather than rounded ones. Texture and biting characteristics vary according to cultural preference: for Japanese udon, the texture should be soft and elastic. For Chinese Mandarin ("gan mian") and Cantonese ("kon mien"), the texture should be firm and chewy. Wheat and flour quality characteristics that contribute to these desired quality traits include good milling characteristics with ease of bran separation, bright endosperm, and flour color. For udon noodle, weak but extensible gluten, relatively high starch paste viscosity, low amylase activity, and lower starch amylose content are desirable. Usually soft white wheat is preferred. For white salted Chinese noodles, high-protein, stronger gluten flours are preferred, similar to those used in bread. In this case a normal level of starch amylose contributes to a firmer texture.

Alkaline noodles, as the name implies, are prepared using alkaline salts. A typical formulation would include 1–3% NaCl and 1–3% alkaline salts (flour weight basis). Alkaline salts, often referred to as *kan sui* ("can soo-ee," or "can-swee"), may be comprised of combinations of potassium and sodium salts of carbonate (K_2CO_3 and Na_2CO_3) and/or sodium hydroxide. Like white salted noodle, the main quality attributes of alkaline noodle are color, appearance, and texture. Color should range from creamy white to yellow. Appearance should be bright, not gray or dull, with as few specks as possible. The color should be stable and should not deteriorate during storage. Texture should be elastic rather than weak and soft, and should not soften or deteriorate during storage. Milling quality, endosperm color, gluten characteristics, and starch pasting quality all contribute to alkaline noodle quality. Alkaline noodles are typically prepared from higher-protein, stronger-gluten hard wheats, similar to those used for bread.

Two popular variations on the basic, simple formula include buckwheat and egg noodles. Buckwheat noodles, called soba, are made from wheat flour and buckwheat (*Fagopyrum esculentum* Moench.): about three parts wheat flour to one part buckwheat flour. Egg noodles, as the name implies, are prepared using eggs, and may be prepared using whole fresh eggs as the only source of formula liquid. In the US, dry egg noodles contain at least 5.5% egg solids.

Convenience is an important force that drives consumer spending. In the US, Japan, and Korea instant noodles which have been fried in hot oil, cooled, and packaged provide a quick and easy meal. Some are packed in ready-to-serve cups or bowls and almost all come with a seasoning sachet.

"Ready-to-Eat" Cereals and "Breakfast" Foods

Although many rolls, breads, noodles, etc., are eaten at the first meal in the morning, "ready-to-eat" (RTE) cereals and breakfast foods are popular in many parts of the world. RTE foods are cereal-based foods which require no cooking. Generally flaked, extruded, steamed, or shredded processing gelatinizes starch, denatures protein, and develops texture. Most of these foods are very low moisture content and consequently can be stored for long periods of time. Popular brands in the US are produced by General Mills, Kellogg's, Nabisco, Post, and other companies. These and similar products are made from wheat, rice, corn, and other cereals. Soft white wheat grain with large kernels is preferred for easy flaking and better color after roasting. More traditional wheat-based "breakfast" foods include products similar to oat meal-porridge and other cooked cereals.

Pasta and Durum Wheat Products

Alimentary paste, or "pasta," is prepared from extruded dough pieces of various shapes and sizes, usually dried during production, and later boiled and consumed. A common classification is based on whether the pieces are long or short (e.g., spaghetti versus macaroni). In contrast to the noodles described above, pasta is prepared from durum (*Triticum turgidum* var. *durum*) semolina. Although Italian in origin, pastas – such as spaghetti, macaroni, lasagna, and fettuccine – are now a common part of culture and language in the US and worldwide. Some pasta products contain fillings, such as tortellini and ravioli with cheese or meat.

The production of semolina is the primary goal of durum wheat milling. Semolina is simply larger-sized pieces of endosperm (compared to flour), free of adhering bran. Semolina size ranges from about 130 to 550 μm. In addition to the particle size of semolina, color, vitreousness, and protein quantity and quality are key quality traits. Higher levels (>13%) of strong gluten are preferred. The protein must form a continuous matrix to entrap the starch granules so that the pasta surface does not become sticky during cooking. In most cases, the addition of hexaploid wheat to pasta is considered undesirable and is prevented by law in some countries.

As mentioned earlier, pasta is an extruded product. Semolina is first mixed with water in an approximate ratio of 30 : 100 (water : semolina) into a stiff

dough. The dough is forced at high pressure through a die to produce the desired shape and size. The pasta is then collected and dried. Mixing, kneading, and drying are critical steps to successful pasta manufacture.

Other nonpasta durum wheat products include primarily bread, couscous, and bulgur. Durum bread is prepared from durum flour rather than semolina. The salient differences between typical hexaploid and durum wheat flours are coarser particle size, higher starch damage, higher water absorption, strong gluten with low extensibility, high dough stability, and yellow color of durum flour. Due to the high levels of damaged starch and water absorption of durum flour, durum bread stales much more slowly and consequently has an extended shelf life, compared to hexaploid wheat bread.

Couscous and bulgur are precooked, unleavened foods traditionally consumed in North Africa and the Middle East. Couscous is prepared from semolina by hydrating, mixing, steaming, drying, and size-fractionating the resultant particles. Couscous is then rehydrated with oil and meat and/or vegetable sauce when eaten. Bulgur, on the other hand, is prepared from whole or cracked kernels by soaking in water, parboiling, drying, and grinding. Prior to eating, bulgur is boiled or steamed.

Starch and Gluten

Wheat starch and gluten each have unique compositions and properties. Consequently, it is useful to isolate each in relatively pure form. Separation is accomplished through one of the three general methods: Martin and batter processes, and differential centrifugation. All three typically employ roller-milled flour, usually harder, higher-protein, stronger gluten wheats. The Martin process mixes flour and water into a dough and then washes out the starch and water-soluble constituents. Usually, NaCl is included to promote gluten agglomeration. Small aggregates of agglomerated gluten are recovered by sieving. In both the Martin and batter processes starch is recovered through centrifugation. Differential centrifugation separates nonaggregated gluten from starch, the main advantage being reduced wash water. Once separated, most gluten is dried and sold as a free-flowing powder.

The primary reason for starch–gluten isolation is to obtain vital gluten. "Vital" refers to the fact that the isolated gluten retains its functional viscoelastic (and therefore bread-improving) properties. The main use of vital gluten is in yeast-leavened bread products, especially variety breads where the load of nonfunctional ingredients is relatively high and flour protein is diluted. Vital gluten helps maintain product volume and internal structure. During isolation, controlled drying is key to maintaining the functionality of vital gluten. Excessive heat denatures gluten and renders it nonvital. Nonvital gluten, though of little value in baking, does find application in pet foods and other uses.

In the US and other countries with large quantities of maize, wheat starch is of minor importance, gluten being the primary reason for starch–gluten separation. In countries such as Australia, however, starch is an important co-product. After isolation, starch is usually further processed into sugar syrups, ethanol, and specialty modified starches. In this regard, wheat starch use parallels maize.

Assessment of Flour Quality

The main reason for assessing flour quality is to predict its performance in commercial applications – either processing traits or end-product traits. Assessment of flour quality can be classified into two categories: end-product tests and component tests. Both have their own merits and are described below. End-product tests tend to produce a summation of quality – the sum total of all the components of quality as well as their interaction, if any. For this reason, end-product tests are generally considered the best predictors of commercial end-product quality. However, end-product tests usually require more personnel, time, flour, and equipment compared to component tests. Component tests tend to assess one or more fundamental property or component of flour, such that end-product quality may be predicted. The advantage of component tests is that they are generally conservative of resources, quick, and amenable to large numbers of samples. Component tests also have the advantage of more precisely identifying why a particular flour may have better or poorer quality. The main shortcoming of component tests is their limited ability to capture all aspects of commercial end-product quality.

End-Product Tests

End-product tests typically use a scaled-down, semi-, or nonautomated procedure that mimics the large-scale industrial process. Product formula may match exactly that of the commercial product or may be a simplified, standardized test product. Commonly used standardized end-product tests include pan bread, cookies, and pasta. Additionally, laboratory-scale end-product tests have also been developed for steamed bread, flat breads, bagels, and noodles. Flour quality is assessed on the characteristics of the

prepared product, e.g., the volume and internal crumb appearance of bread loaves, the diameter of cookies, and the cooking loss of noodles and pasta.

Component Tests

The use of component tests for flour quality assessment is founded on the premise that end-product (or processing) quality can be predicted from one or more attributes of the flour. Beyond predicting end-product quality, there is the practical necessity of determining the processing properties of flour so that plant production runs smoothly and efficiently. End-product quality and processing quality are closely linked.

It is the inherent, fundamental physical and chemical properties of wheat flour that make it the single most important and diverse food in the world's diet. It is also these fundamental properties that are characterized, and by doing so, the processing and end-product quality of a flour is predicted. In this context, these properties, or components, of wheat flour may be grouped as protein, starch, water relations, and color. Each of these will be dealt with following.

The quality and quantity of wheat flour is an important basic property. As discussed earlier, it is the viscoelastic nature of gluten that allows gases produced during fermentation to be trapped in the dough, thereby increasing the volume and producing the appealing texture of bread. Likewise, it is these same gluten proteins that can impart a tough or undesirably chewy texture to many cakes, cookies, and pastries.

The quantity of protein is often important to predicting end-use quality. Two main approaches are most common: determination of elemental nitrogen with an empirical conversion to protein, and an empirically derived prediction of protein based on spectroscopy using specific wavelengths of light in the near-infrared (NIR) region. The techniques include Kjeldahl and combustion methods of elemental nitrogen determination, and NIR reflectance and transmission spectroscopy.

The quantitative assessment of protein "quality" or gluten functionality is substantially more challenging and usually empirical. Standard methods exist for the determination of gluten contents (not all protein is gluten and gluten is not all protein). Two other approaches to gluten quality include dough mixers and machines that record and characterize the elasticity and extensibility of doughs. In the first category are the Mixograph and Farinograph. In the second category are the Extensigraph and Alveograph. Recording dough mixers produce a curve from which assessments of gluten hydration, development, strength, and stability can be derived. Additionally, an assessment of optimum flour water absorption can be made. The extensibility of gluten in doughs is assessed by the Extensigraph by uniaxially stretching a dough piece to the point of failure. The Alveograph biaxially stretches a dough piece by blowing a bubble using air pressure. The bubble volume is likewise increased to the point of failure.

Starch can undergo profound physical–chemical changes. These changes relate primarily to the events known as gelatinization and gelation. During the gelatinization process, starch can interact with several times its own weight in water, and in doing so forms a gel structure. The characteristics of this gel are critical to the structure, texture, and quality of many foods. In many instances such as soup thickeners, the concomitant increase in viscosity associated with gelatinization is the main purpose for including wheat flour as an ingredient. Conversely, the hydrolysis of starch to simple sugars provides a ready source of fermentable carbohydrates for yeast fermentation.

Wheat flour is $\sim$75–80% starch on a dry weight basis. The starch content of flour can be measured directly using specific starch-degrading enzymes. The functional performance of starch–starch quality, primarily the gelatinization, gelation, and viscosity properties, is usually of much greater interest than the quantity of starch. Two common methods available for assessing starch quality are the Brabender Visco Amylograph and the Newport Scientific Rapid Visco Analyzer (RVA). Both work on starch–water or flour–water slurries and record viscosity as a function of resistance to stirring during gelatinization and gelation.

In wheat, the factor primarily responsible for differences in starch quality is the ratio of amylose to amylopectin. In hexaploid wheat, three genes code for the enzyme responsible for the biosynthesis of amylose (this enzyme is termed "granule-bound starch synthase"). When all three copies of the gene are present, a "normal" amount of amylose is present – $\sim$23–27% (starch basis). When all three are absent, amylose is less than 1% and the grain is referred to as "waxy" (Figure 1). The presence of one or two genes produces an amylose content of about $18 \pm 2\%$ and $21 \pm 2\%$, respectively. Very small changes in amylose content are associated with dramatic changes in starch functionality.

Sometimes the functional performance of starch has less to do with starch quality *per se* as it does with the presence and activity of starch-degrading enzymes. These enzymes may be of two sources: endogenous, the result of preharvest sprouting, or exogenous, in the form of malt flour or commercial fungal sources which are often added to pan bread

Figure 1 "Waxy" (left) compared to "normal" (right) amylose-content wheat starch gels. Equal amounts of starch of each type were heated (*c.* 95°C) with water under constant stirring in a Rapid Visco Analyzer and then allowed to cool to room temperature. Waxy starch contains no amylose and produces gels which are more translucent, weaker, and viscous.

formulas. The Visco Amylograph and RVA can assess existing starch damage and can also assess potential *in situ* starch damage which might occur during processing. Similarly, they can assess the potential effects of added amylase. The "falling number" test is widely used to estimate sprout damage and is based on viscometry during gelatinization. A weighted plunger is allowed to fall through a gelatinizing sample of ground grain or flour. Aimed primarily at assessing sprout damage, the method also incorporates inherent differences in starch gelatinization properties.

Starch quality and performance are also affected by mechanical starch damage. As noted previously, damaged starch absorbs more water and is more susceptible to enzymatic attack. Although the level of starch damage is highly influenced by grain hardness, milling procedures have a major impact and different millstreams will differ markedly in damaged starch. Quantitative measures of starch damage rely on the susceptibility of granules to α-amylase attack or ability to bind I_2/KI.

The third fundamental aspect of flour functionality relates to water relations. Even though gluten hydration during mixing and starch gelatinization are major contributors to water relations, water relations are often examined independently because (1) there are additional, often poorly characterized sources of water uptake, and (2) often the simple sum total expression of these various components is of immediate interest to the food processor.

Assessment of water relations can be made by observing properties of doughs or from the way in which flour interacts with excess water or various solvents. As noted above, most of the methods used to assess gluten strength also provide an estimate of the optimum hydration level of a dough. "Solvent" tests now include methods which employ water, ethanol–water, sucrose–water, and Na-carbonate–water. The amount of solvent retained by the flour after hydrating and centrifuging is diagnostic of flour constituents.

Finally, color is an important consideration, because food must be appealing to the eye as well as the other senses. Color in the sense of end-product quality may be considered in the context of the production or maintenance of desirable color or the prevention or reduction of undesirable color. A few examples are the golden-brown color of bread crust which results from Maillard reaction, the bright yellow color of pasta, and the prevention of darkening of Asian noodles.

Although visual assessment of color is often satisfactory, the development of hand-held reflectance colorimeters has made triaxial quantitation of color common (Figure 2). The importance of inherent color systems associated with wheat and flour varies, depending on the particular end product. For example, the whiteness of a soft wheat flour may be crucial to the appeal of an angel food cake, whereas it may matter little in a chocolate cake. Two products where color is especially important are pasta and noodles. Pasta requires high levels of yellow pigments to impart a bright, deep yellow appearance. Loss of color during boiling should be minimized. Noodles, on the other hand, must be bright, not dull and should be creamy white at neutral pH and yellow at alkaline pH. Off-colors are unacceptable and generally result from chemical or enzymatic changes. Due to the importance of noodle color (especially brightness), and due to the tremendous range in noodle brightness produced from different wheats, noodle brightness has received considerable attention. A leading culprit in the loss of noodle brightness is the enzyme polyphenol oxidase (PPO). Small-scale

Figure 2 Hand-held color meter used to objectively measure food product color in the triaxial color space ($L^*a^*b^*$) system. When analyzing raw noodle sheets, it is critical to use a standardized color tile for background, as shown.

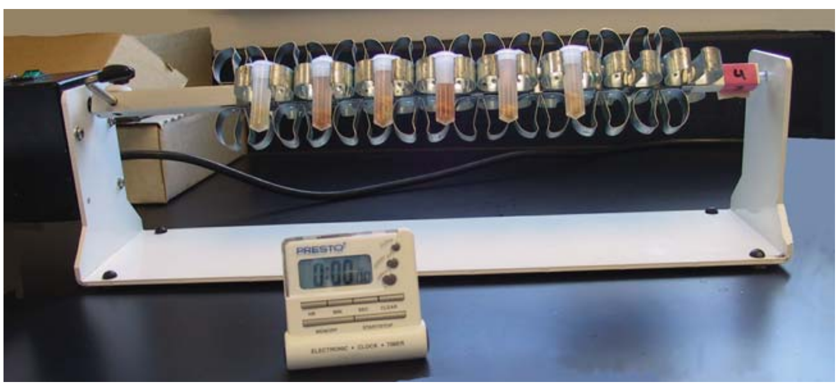

Figure 3 Small-scale assay for assessing PPO levels in wheat grain. PPO activity is associated with noodle darkening; consequently lower levels of PPO are preferable and selected for. Shown are six small (2 ml) tubes which contain 1.5 ml of buffered L-dopa solution and five wheat kernels. The apparatus rotates the samples slowly for 30 min after which the amount of pink product (produced by PPO) is measured spectrophotometrically or judged visually.

assays exist that quickly assess PPO levels in grain (Figure 3).

Lastly, and beyond these four major categories of component traits, there are specific traits unique to certain foods or processes. Additionally, there are three practical considerations that are highly dependent on milling and on whether the wheat is hard or soft. These are flour moisture content, ash content, and particle-size distribution. Flour in the US is targeted to 14% moisture content and there are several methods for its accurate measurement, similarly ash. Ash is an old but extensively used method of assessing milling extraction and therefore things such as protein quality and color. The central part of the kernel is low in ash while the bran is high. Flour from the central endosperm generally contains more functional protein (better protein quality) as opposed to flour from near the bran or outer portion of the kernel. Similarly, bran often contributes undesirable colors. Soft wheats produce flours of smaller particle size and lower starch damage; durum wheats are at the other end of the scale, producing coarse semolina. Hard hexaploid wheats are intermediate.

Intrinsic Quality of Wheat Grain and Grain Lots

Grain hardness (kernel texture) is arguably the single most important aspect of wheat utilization (Figure 4). Durum wheats lack the genes responsible for softness and consequently are very hard, whereas hexaploids may be soft or hard, depending on the allelic state of these genes. Also, overlaid on this genetic system is the variation due to the environment. Measures of grain hardness are empirical but commonly used. A physical method, referred to as particle-size index (PSI), relies on the fact that upon grinding, soft wheats produce finer meals and flours. By sifting and weighing, wheats may be classified as soft or hard, or assigned a quantitative numerical value. More recent developments in the assessment of grain hardness include an NIR spectrophotometric method and a single kernel crushing device, the Perten SKCS 4100 (Figure 5).

Figure 4 Cookies baked from soft (left) and hard (right) wheats which differ only in their *Hardness* gene. Near-isogenic soft (*Ha*) and hard (*ha*) wheat lines were milled and their flours baked using a standard AACC cookie formula.

Figure 5 Perten Single Kernel Characterization System SKCS 4100. This instrument weighs individual wheat kernels before crushing them between a rotor and load cell-mounted crescent. The load cell interprets the crush characteristics as a quantitative measure of kernel hardness. Kernel outer diameter and moisture content are also measured. The computer monitor shows the four different stepped histograms of weight, diameter, hardness index, and moisture. The standard method measures 300 kernels in less than 5 min.

In addition to hardness, kernel mass and morphology affect end-use quality. Generally, millers prefer uniformly large, well-filled (plump) kernels. The measurement of kernel mass is typically expressed in terms of thousand kernel weight, whereas kernel morphology is approximated using bulk density (hectoliter or bushel weight). The Perten SKCS 4100 device provides measures of kernel weight and outer dimension, as well as hardness and moisture.

Protein quantity and quality were discussed above for flour. Since there is a strong and direct relationship between flour protein and grain protein, assessing these traits in grain is often desirable. The quality of protein is primarily controlled by genetics. The quantity of protein, however, is highly influenced by the environment including cultural practices, most notably nitrogen fertilizer. A range of 7–17% protein is possible within one cultivar. The methods of determining grain protein are similar to those employed for flour. Whole-grain NIR methods are particularly convenient and obviate the need for grinding.

Moisture content determines the storability of grain, the relative concentration of other kernel constituents (e.g., protein), and the amount of additional water needed during tempering before milling. For safe storage, wheat must have no more than 12–13% moisture content. The reason grain moisture is critical for safe storage relates to the growth of various molds. In this regard, moisture, time, and temperature all interact to affect grain storage.

An intrinsic quality trait of grain is soundness or sprouting. Preharvest sprouting occurs when rains and high humidity coincide with grain maturation and delayed harvest. The reason sprouted grain is often considered to be of inferior quality relates to the presence of carbohydrases, proteases, and other hydrolytic enzymes normally associated with germination. The two main methods of assessing sprout damage are by visual inspection of kernels (noting pericarp rupture over the embryo or other signs of germination) and the falling number assay (see above). Other methods used for flour or starch, or specific to the detection of individual enzymes are amenable, though not commonly used for the analysis of grain.

Finally, the quality of grain and grain lots may be reduced by the presence or prior activity of molds, insects and rodents, seeds of other species, nonmillable material, stones, etc. The presence of pesticide residues is increasingly an important issue. The presence of mycotoxins produced by *Fusarium* fungi and proteases resulting from *Eurygaster* insect are of particular concern to wheat.

Rice

Rice is the third-leading cereal in terms of world production and is the staple food for over-half the world's population. The rice kernel, when harvested, has an adhering lemma and palea (husk), and is referred to as "paddy" or "rough" rice. The husk is removed during milling producing what is known as "brown" rice – the "naked" kernel has the brown bran layers present. "Polishing" removes the bran and produces the resultant white "polished rice" that is commonly eaten after boiling.

Botanical classification of rice includes *japonica* (short grain) and *indica* (long grain), although a range of kernel lengths is observed. In the US, short-, medium-, and long-grain rice varieties are developed, each with a specific set of quality criteria. Rice is classified also according to amylose content, gelatinization temperature, and whether it is "aromatic" – indicating that it additionally has desirable aroma components.

Rice quality is assessed in terms of grain appearance, milling quality, and cooking quality. Kernel size and shape, length, length/width ratio, whiteness, gloss, translucency, uniformity, and moisture content are quality criteria applied to rice grain. Rice milling removes the hulls, bran, and germ while minimizing kernel breakage. The majority of rice is consumed in polished form, even though removing the bran greatly decreases the nutritional content of the grain. Milling quality is based primarily on the yield of whole grain polished rice ("head rice"). Broken grain is usually worth only about half as much as whole grain. Breakage results from primarily checking and chalky grain. Checking results when harvesting and threshing are delayed or when drying is too rapid and fissures develop in the kernel.

The preferred texture and flavor and other cooking characteristics of rice vary among consumers. Usually short- and medium-grain varieties become somewhat sticky upon cooking, whereas long-grain rice is harder and maintains the integrity of individual kernels. Generally, cooking quality is evaluated directly with measures of water uptake, optimum cooking time, volume expansion, solids loss to the cook water, etc. Stickiness and other eating quality parameters are evaluated by sensory analysis directly or via instrumental analysis.

Due to the inherent subjectivity and time-consuming nature of these cooking and eating quality tests, predictive tests have been developed and are extensively used. These often attempt to relate chemical and physical properties of the grain to the desired subjective characteristics of the cooked rice. The two most important physico-chemical properties related to cooking quality in rice are gelatinization

temperature and amylose content of the starch. Starch comprises ~90% of the total dry polished rice. Starch exists in compound granules similar to oats. The determination of amylose content and gelatinization temperature and the relationship between these two factors have been the major indirect means of selecting for cooking quality in rice breeding programs. The use of the amylograph and RVA has been extensive in rice breeding to assess starch gelatinization and pasting behavior. Other tests include alkali spread, gel consistency, and protein content.

Maize

The vast majority of maize produced worldwide is used as animal feed (Table 1). Consequently, that use is reviewed below. Of the remainder, sizable quantities are used in the wet and dry milling industries, which are described below. In addition, some maize is ground directly for human consumption, and some is ground simply as a preparatory step in starch conversion for ethanol production. In the Americas, maize has long been a staple food, and a traditional means of preparing maize is through the production of masa, wherein maize is steeped in lime water, ground, and the majority of bran is separated and discarded. White maize production is estimated at 65–70 mmt and is used mostly for food. For all food uses, common quality criteria include mold and mycotoxin concerns and the general physical health of the grain.

Maize is a single species but has several important kernel types resulting from simple genetic systems. By far the most important commercially is yellow dent. Other types include flint, flour, pop, sweet, white, and pod. Some endosperm mutations which involve alterations in starch biosynthesis include the sweet corns, high amylose, and waxy maize.

Wet Milling

About 10% (or 50 mmt) of the annual worldwide production of maize is used in the wet milling industry, of which about half occurs in the US. The primary aim of wet milling is the recovery of starch which is used to make sweeteners, ethanol, modified and unmodified industrial and food starches, etc. Wet milling, as the name implies, involves steeping maize kernels in water and sulfur dioxide to loosen the bran and germ from the endosperm. The germ is recovered and used to isolate oil; afterwards the remaining germ tissue is approximately one-fifth protein and is valuable as a feed product. Starch is separated from cell wall material (fiber) and endosperm protein (gluten) through a process of grinding, hydrocyclones, and filtration. Yield of starch is ~65–68%, fiber 11–13%, germ 7–8%, gluten meal 5–6%, the remainder steep water and loss.

Maize for wet milling should have a high starch content and be low in mycotoxins. Kernels should be well filled; low test weight indicates poor grain filling, whereas high test weight indicates that kernels have a high vitreous to starchy endosperm ratio. Vitreous endosperm, such as that found in flint maize and a portion of yellow dent maize, is undesirable due to the slower steeping and processing time required. Mechanically damaged and broken kernels are also undesirable. Lastly, the drying regimen of maize after harvest is critical to high-quality grain – too high and steeping rates drop, grinding is more difficult, and there is a loss of protease activity and starch release. Endogenous proteases, along with sulfur dioxide, contribute to starch release. Some waxy maize (having 0% starch amylose) is grown on contract for the wet milling industry.

Dry Milling

The primary aim of dry milling is the production of flaking grits – the most valuable product. Flaking grits are large pieces of vitreous endosperm. Naturally, not every maize kernel yields a couple flaking grits and even those that do also produce some quantity of smaller pieces of endosperm. Depending on the size of the particle, it may be classified as coarse or regular grits, or meal or flour. To maximize the yield of flaking grits, the maize kernel is tempered for a short time to loosen the bran and germ (to ~18–24% moisture and less than 1 h). The first stage of the grinding process is to remove and recover the germ. Oil is generally extracted from the germ as a co-product; the remaining tissue is rich in protein and is used as animal feed. All of the unrecoverable material from dry milling, primarily bran recovered by aspiration and spent germ, becomes "hominy feed."

The primary quality criteria for dry milling is a high proportion of vitreous endosperm in a yellow dent variety, free of mold, and mycotoxins. Stress cracks from poor drying are undesirable because they reduce the recovery of grits. Even though flint maize is entirely vitreous, it is actually less desirable for dry milling because its more spherical kernel morphology is not conducive to producing grits.

Popcorn and "Sweetcorn"

All maize kernels have some propensity to "pop" – i.e., explode when superheated steam inside the lumen of each starch granule reaches sufficient pressure to

cause the pericarp to suffer a catastrophic failure. However, specific varieties of popcorn have been bred to maximize these alluded to physical phenomena. Popcorn kernels tend to be nearly spherical and uniformly vitreous endosperm. The pericarp must be sufficiently strong to facilitate a high internal pressure before failing. However, once popped, the pericarp is undesirable from the consumer standpoint and therefore its thickness is held to a minimum.

Quality criteria include the lowest possible levels of mold, mycotoxins and insect damage, hard endosperm with high test weight, and high popping volume with low percentage of nonpopped kernels.

"Sweetcorn," sweet maize, is simply vegetable corn that is eaten prior to full kernel maturity; its flavor is enhanced through a number of endosperm mutations that increase the sugar content at the expense of starch biosynthesis. Sweetcorn may be eaten as "corn on the cob" after boiling or cooking, or as a canned or frozen vegetable. Hominy is a maize product produced from white- or yellow-kernel maize using alkali to remove the bran. It is popular in the southeastern US.

Barley

Barley has three distinct end uses: feed, alcoholic beverages, and human foods. The vast majority is used for feed followed by malt and lastly food. About 75% of the world's barley production is used for feed, whereas only $\sim$5% is consumed as food. Morphologically, there are two major types of barley, two row and six row, which refer to the number of vertical rows of kernels on the spike (ear). Two-row barley tends to have plumper, more uniform kernels, and therefore may have an advantage in malting. Six-row barley tends to yield better. However, these generalizations have many exceptions depending on the region and the past history of breeding. Speciality types of barley include hull-less, high amylose, and waxy. Feed barley quality is reviewed in the section given below.

Malt quality is related to kernel size uniformity, kernel plumpness, and color. Additionally, protein content and germination rate and uniformity are critically important. Germination should be preferably over 95%, approaching 100%. Like all cereals, there is a concern for microbial contamination including mycotoxins. Naturally, the grain lot should be free of extraneous material, weed seeds, stones, filth, etc.

Generally, barley malt is made from pure varieties, specifically bred for malt production. Occasionally a carefully controlled blend of two malt varieties may be used. The two leading roles of barley malt in brewing are to supply a high quantity of hydrolytic enzymes produced during the germination process, and a high level of "extract" which provides the fermentable substrates during brewing. The hydrolytic enzymes break down the starch, protein, and β-glucan during fermentation. The amount of soluble extract is directly related to the amount of beer that can be produced from a given quantity of malt. A negative correlation exists between barley protein and the amount of extract produced from malt. Malt should additionally have low levels of undesirable compounds such as β-glucan, polyphenols, and dimethylsulfide precursor.

The most common method for testing the potential malting quality of a barley sample remains the malting of the sample. Micro- and pilot malting procedures are used. Afterwards, analyses typically measure the amount of extract that a malt will deliver into solution under standard conditions, amount of solubilized protein, and amount of enzymes. Other useful tests measure moisture and protein contents, germination, kernel size, and plumpness. Varietal purity is also of interest but is technically more challenging. Currently, some major exporters are testing and verifying the varietal composition of barley malt shipments using polymerase chain reaction which can exploit unique DNA sequences.

The leading use of food barley is pearled barley kernels added to soup. Minor uses include barley flour, rice extenders (Japan), and couscous. Barley for pearling should have white endosperm color, colorless aleurone, and should be uniformly floury or vitreous (not a mixture).

Sorghum and Millets

The US is the leading producer of grain sorghum, followed by India and Nigeria. In the US essentially all sorghum is used as animal feed, similar to maize. Feed use is covered in the section given below. In other parts of the world, sorghum is an important food. Sorghum is dry-milled into grits and flour for baking, brewing, porridge, snack foods, malt, and other minor uses.

A key quality trait in sorghum is the presence or absence of tannins and pigments in the outer layers of the kernel. Pericarp color is controlled by two genes and confers brown, yellow, or red colors. Testa color is controlled by one gene and can be brown or purple. Yellow endosperm cultivars have a high level of carotenoid pigments. Pericarp thickness affects how these various kernel colors are perceived.

Tannins and other phenolics found in some sorghum cultivars are distinctly antinutritional. However, these compounds afford some protection

against insects and birds, features that outweight their disadvantages in some locales. Nevertheless, white sorghums generally produce higher-quality foods. Quality criteria are similar to maize and include kernel hardness, density, and ease of pericarp removal.

Millets include a number of distinct grass species and are generally grown in harsh, dry climates by subsistence farmers. India and Nigeria are the leaders in millet production. Common type names include pearl, foxtail, finger, and proso millet. Most are consumed after decorticating by hand in a large mortar and pestle. Consequently, pericarp removal should be easily achieved and the endosperm should be hard and vitreous; color should be white with low pigment and tannin contents.

Oats

Oats, like rice, are harvested with an adhering husk (lemma and palea) which is removed during processing. Oats notably have a high oil content (6–8% lipid in the endosperm compared to ~1% for wheat), and are rich in β-glucan. Most are used for feed; an estimate in the 1990s placed food usage at ~25% of world production. The primary food uses of oats are rolled oats, steel-cut groats, quick oats, oat flakes, oat bran, and oat flour. Because of the high oil content and the presence of lipid-degrading enzymes (lipase, lipoxygenase, and peroxidase), oats and oat products are heat-treated to inactivate these enzyme systems. Rolled oats are produced by passing whole groats through steel rollers which produce flakes. Steel-cut oats are simply groats cut into two to four pieces. The pieces are in turn generally also flaked, producing quick oats and oat flakes.

The primary food use of oats is a hot porridge. Consumer interest in convenience has generated "instant" forms of this traditional food. Oats are also used to make "breakfast" cereals, perhaps the most notable in the US is the extruded product "Cheerios." The primary quality criteria for oats include presence of other cereals in grain lots, especially barley, because the barley kernel is so similar that it is very difficult to remove. Barley contaminates the oat product with its hull, which is highly objectionable to consumers. Other criteria include test weight, percentage of hulls (groat yield), presence of mold and mycotoxins, "thins" (kernels that pass through a 1.98×19.05 mm screen), and free fatty acid content (an indicator of prior kernel damage, poor storage, etc.).

Rye and Triticale

Most rye is produced in Northern Europe and Russia where it remains a traditional, staple food. Russia, Poland, and Germany produce over 70% of the world's production of rye. Production of triticale, which is a man-made species derived by crossing wheat and rye, parallels rye. Germany and Poland are the leading producers and account for over 50% of world triticale production.

The unique feature of rye is its high pentosan content. Pentosans impart high water-holding and viscosity to the dough which allow rye to be baked into bread. Rye is essentially the only cereal besides wheat which has traditionally produced a yeast-leavened loaf of bread. Rye bread, however, is very dark and very dense (consumers choose rye bread for these specific attributes). Often rye and wheat flours are blended to prepare "light rye" and "dark rye" breads. The primary quality criteria of rye are similar to other cereals, absence of mycotoxins and molds. Additionally, because of rye's biology and area of production, sprouting and ergot are primary concerns. Triticale is essentially an animal feed. When triticale does find its way into human foods, its quality criteria are similar to those of rye and wheat.

Feed Uses of Cereals

According to recent estimates, ~16% of world wheat production is used for animal feed. For rice, the percentage used for feed is less than 3%, whereas for maize the figure is 67%. For the other cereals, feed use ranges from 75% for barley, 50% for sorghum, and 7% for millets.

In terms of animal feeds, cereal grains are primarily a source of energy. Since energy is the most expensive component of feeds, cereals play a central role in rations, especially those for monogastric animals such as poultry and swine. For the major cereals, metabolizable energy (ME) ranges from about 11 to 14 MJ kg^{-1}. Over 80% of this ME comes from starch.

Cereals also make an important contribution to protein needs as well. Although cereals may contribute over one-third of the protein required in swine and poultry rations, they are all notoriously deficient in the amino acids lysine, methionine, and threonine. Alternative sources of protein, such as soybean meal, which include higher relative quantities of these amino are required.

Various strategies have been developed to address the shortcoming of cereals as feeds. With the exception of maize, cereals are deficient in the essential fatty acid linoleic acid. High oil content maize provides a more concentrated form of energy. Opaque 2 and other types of maize have altered and more balanced protein composition. The starch of waxy maize and barley may have greater digestibility. Generally, with

these variants, the cost of production and segregation must be considered against the benefit to the feeder.

With the exception of potassium and phosphorus, cereals are deficient in minerals essential for animal growth and reproduction. Potassium is readily available, phosphorous much less so (to monogastrics). However, researchers now have mutations that free up most of the grain's phosphorous, which is normally "locked up" in the form of phytic acid.

Specific Issues

Wheat pentosans are considered to be an anti-nutritional factor, especially for poultry. Similarly for barley, the issue is β-glucan, and is mostly a problem associated with poultry. Tannins are anti-nutritional factors for brown sorghums.

With the exception of white-kernel varieties, maize is high in carotenoids. Maize gluten meal is a concentrated source of carotenoids and is a primary source of these pigments for the poultry industry which often desires a highly yellow yolk or yellow carcass fat. During wet-milling, carotenoids are concentrated 12-fold in this gluten meal.

Barley hulls reduce the ME of rations for monogastrics but are of little concern for ruminants; the hulls may actually be beneficial by reducing the rate of rapid starch breakdown which causes acidosis or "bloat." Hull-less barley has nutritional qualities similar to wheat.

Oats have been traditionally an animal feed. Although they have a good balance of protein, fat, and carbohydrate, they have been largely displaced by cheaper alternatives. The hulls reduce energy concentration by $\sim$25%. However, oats are still the preferred feed for horses. For race horses, quality criteria of buyers may be more exacting than those of food processors. Opinion varies as to whether hulled or hull-less oats are better.

Quality Criteria

Cereal grain for feed should be low in mold and mycotoxins, lower for monogastrics than for ruminants. Grain should also be low in smut and bunt (*Tilletia* sp.) spores.

The primary means of assessing feed quality is through proximate analysis: moisture, protein, and ash. Measures of ME and protein digestibility are substantially more involved (requiring live animals) and not amenable to grain receival stations. Test weight and general appearance of the grain are crude indicators of feed value and can be used to reject individual lots. Naturally, grain lot contaminants pose a variable level of concern based on their nature (e.g., kernels of other cereals versus stones or chaff).

For most poultry and swine rations, cereals are hammer-milled, because smaller particle size increases digestibility. The proportion of vitreous versus nonvitreous yellow dent maize kernels affects grinding energy. Barley and sorghum are often steam-flaked for feedlot cattle.

In addition to the use of the entire cereal kernel in feeds, it should be remembered that the processing of all cereals for human foods or industrial products generates by-products which largely become animal feeds. Examples include wheat bran, maize gluten feed, and brewers spent grains.

Protein Chemistry

F Bekes, CSIRO Plant Industry, Canberra, ACT, Australia
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The main source of protein for the human diet comes from the cereal grains (*see* **Cereals**: Overview). On the one hand, cereal-grain protein is eaten directly in many processed forms as the grains themselves. The second route is indirect, in the form of animal products, such as meat and eggs, following the feeding of cereal grains to animals.

The major cereal grains of importance in the human diet are wheat, barley, rye, rice, maize, and sorghum (*see* **Cereals**: Overview). In these cases, the protein part of the grain is important nutritionally and also for functional purposes, relevant to the processing of the grain. Of these, wheat is unique because of the dough-forming properties of its storage proteins, known as "gluten" when formed into dough.

Historical Perspective

Historically, the proteins of the cereal grains have played a significant part in the civilization of mankind, through their role in providing a reliable source of amino acids, the essential dietary compounds that are the building blocks of proteins in the body. This source of dietary proteins could be obtained via agriculture, permitting the establishment of a permanent dwelling place, providing an important change from the nomadic life of the hunter–gatherer way of life. The establishment of permanent towns led, in turn, to specialization of occupation, and to opportunities for mankind to pursue cultural pursuits and scientific enquiry. However, it is only in recent centuries that the chemistry of proteins has been elucidated.

One of the first proteins to be obtained in reasonably pure form was gluten, because it could be prepared so readily (by the washing of dough). This important experiment, first reported by the Italian scientist Beccari in 1729, is simply performed in the home kitchen. To do so, a dough is mixed by adding water, a little at a time, to wheat flour until a cohesive mass is formed. This dough is kneaded between the fingers under a gentle stream of water from the tap. If a glass is placed underneath, a milky-white stream of starch can be caught in the glass, whilst the dough in the fingers becomes smaller and tougher. The gluten ball held in the fingers is mainly protein, separated very simply from the starch that settles in the bottom of the glass.

This gluten-washing procedure has since become very big business internationally, because the gluten thus isolated is needed for bolstering the protein content of a wide range of food products – bread especially, but also breakfast cereals, meats, cheeses, snack foods, and texturized products. Nonfood applications include pet and aquaculture feeds, biodegradable plastics, films, coatings, adhesives, inks, cosmetics, and pharmaceuticals (*see* **Gluten and Modified Gluten**).

The word "protein" was proposed by the French scientist Berzelius, writing to the German scientist Mulder, with the appropriate meaning of "primary substance," as recently as 1838, long after the acceptance of the terms for specific types of proteins, such as "gluten," "zymom," and "fibrin." Early concepts of protein chemistry imagined it to have the complex formula $C_{20}H_{31}N_5O_6$, meaning that 20 molecules of carbon (C) were compounded with 31 of hydrogen, five of nitrogen, and six of oxygen. The dogma of those early days also maintained (incorrectly) that this complex was absorbed (unchanged) directly by the intestine. It is now known that dietary proteins are hydrolyzed to the component amino acids for absorption into the blood stream.

Late in the nineteenth century, the American scientist Thomas Osborne studied the proteins of many edible grains, using a succession of solvents to extract diverse classes of proteins from the crushed grain. As a result, he proposed the generic names of "albumin" (extracted with water), "globulin" (extracted by salt solution), "prolamin" (extracted by 70% aqueous ethanol), and "glutelin" (extracted by dilute acid). These major classes of protein have continued in use, but their definitions have been refined, and it has become clear that any one of these protein classes contains a large number of distinct but related proteins.

What Is a Protein?

It is now known that protein molecules are linear polymers of amino acids. There are ~20 different amino acids, each of them having the combination of an acidic group ($-COOH$) and a basic group ($-NH_2$), with a side chain that provides the essential difference between all of them. The amino acids are joined together by peptide bonds to form a polypeptide chain, by the formula (for two amino acids, 1 and 2)

$$R_1{-}COOH + H_2N{-}R_2 \rightarrow R_1{-}CO{-}NH{-}R_2 + H_2O$$

The sequence and specificity of the amino acids are "spelt out" exactly in the genetic code of the genes, thereby ensuring that the protein will be made in the same manner each time in the specific species and tissue (*see* **Genomics** and **Proteomics**). For this reason, the determination of protein composition is a valuable means of establishing variety identity (*see* **Variety Identification of Cereal Grains**).

It is amazing that the relatively simple chemical structure of the protein can produce a great diversity of properties that are found in proteins, such as enzymes and epidermis, hair and horn, feathers and flagella, silk and sinew, and even spider's web. The diversity depends on the selection and sequence of the amino acids, plus the length of the protein (polypeptide) chain. Further diversity is provided by cross-linking between polypeptide chains, and from linking to accompanying molecules (lipids, carbohydrates, or metal ions). The resulting protein molecules are large compared to many compounds, with molecular

weights often in the range 10–100 kDa (1 Da being equivalent to the mass of a hydrogen atom). Some proteins are much larger, the largest glutenin proteins of wheat gluten having sizes extending up to tens of millions of Daltons.

Why Is Protein Important?

First, the protein component of the grain is critical to the grain's role as the beginning of a new plant. The grain protein has the natural purpose to serve as a reserve of amino acids for the embryo (germ) to draw upon during germination. On the other hand, the grain protein is important for the grain-processing industry, because it is often the most important part of the grain in determining processing quality.

Protein's importance cannot be attributed to it being the component present in the highest proportion of the grain (Figure 1). In fact, starch is the most prolific component of the cereal grain. After starch come protein, lipids (fat), and nonstarch polysaccharides in relative abundance (*see* **Cereals**: Overview). The protein content of cereal grains ranges from ~8% to 15% of the grain weight (Table 1). Even for certain grain species, the actual protein content covers a range of values, depending on the genetic potential of a specific variety of that grain species, and on the nutritional status of the plant (*see* **Barley**: Agronomy and **Wheat**: Agronomy).

The protein components may be considered as the most important of the range of chemical components in the cereal grain. The protein fraction contains the many enzymes that are essential for the synthesis of all the other chemical components of the grain, and also for their breakdown during germination. In the mature grain, a large proportion of the protein fraction serves as a storage for amino acids (polymerized in linear chains as proteins), which in turn are supplied to the growing plant during and after germination.

Most of the protein is in the endosperm of the grain (the part that becomes white flour after the milling of wheat), because the endosperm is the largest part by mass. However, the proportion of protein may be higher in some of the nonendosperm tissues of the grain, especially in the germ (the embryo, which will become the new plant after germination). The barley grain is taken as an example of this in Figure 2. Figure 3 shows the chemical composition of wheat grain, with respect to the distribution of protein (and other components) in its various anatomical parts (*see* **Grain, Morphology of Internal Structure**).

The importance of protein content is seen in the valuation of grain shipments. The "single figure" of the protein content of a grain sample is an important specification in the marketing of most cereal grains. In general, grain of higher protein content commands a higher value. For wheat, a higher protein content indicates better baking quality, and a higher protein content for feed grains provides a richer supply of essential amino acids (irrespective of the proportion of essential amino acids in their storage protein) (*see* **Animal Feed**).

However, malting barley is an exception to the rule that high protein content is desirable, because of the need to have a high starch content to provide a correspondingly high extraction of fermentable sugars in the malting process. Nevertheless, even for malting barley, there is a minimum level of protein (~8%), to ensure that there is an adequate supply of the hydrolytic enzymes needed throughout the malting process.

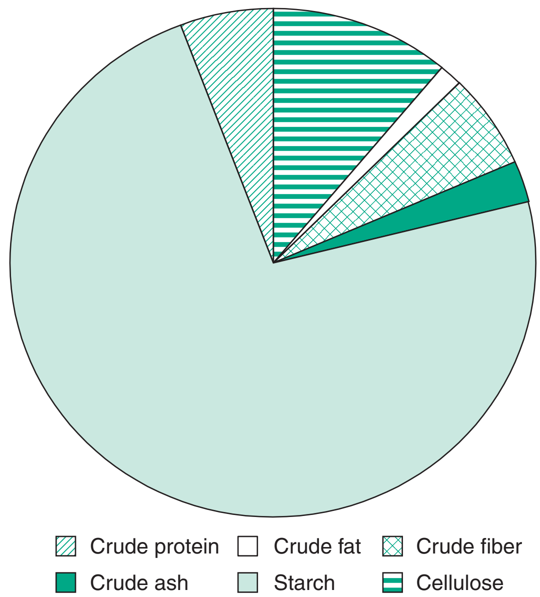

Figure 1 Chemical composition of whole cereal grain.

Table 1 Approximate protein content of the more common cereal species, as percentages of the "as is" weight of whole grain, except for rice

Cereal species	*Protein content (range as % of "as is" weight of whole grain)*
Barley	9–12
Maize (corn)	10–12
Oats (as groats)	12–15
Rice (milled)	8–11
Rye	12–15
Wheat	9–16

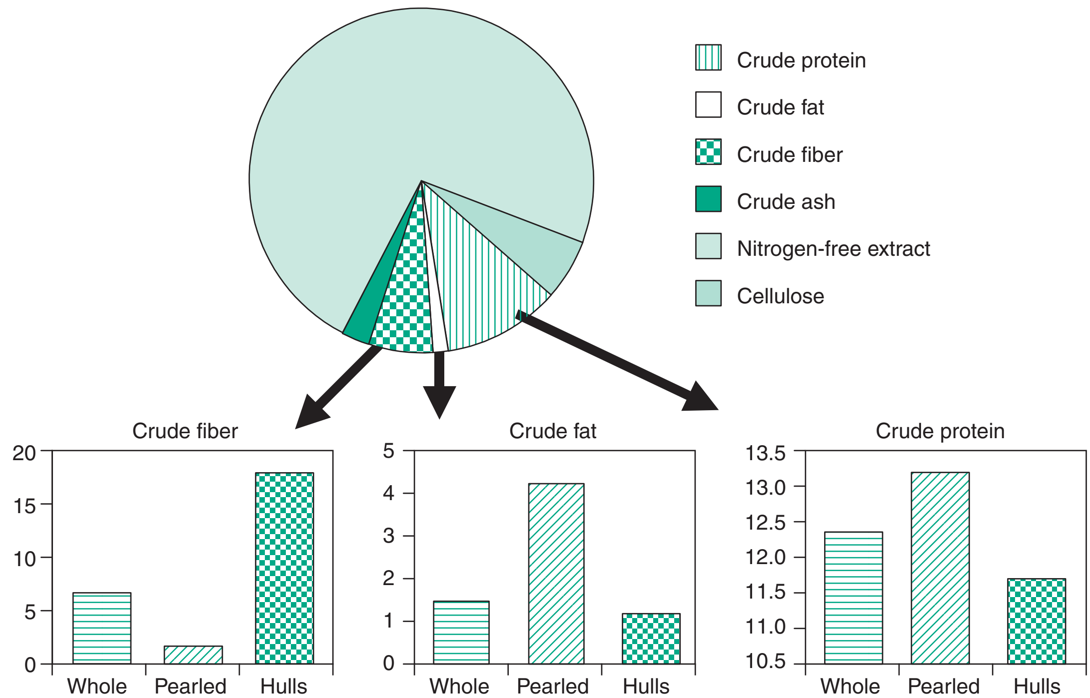

Figure 2 Chemical composition of barley seed and its distribution in its different parts.

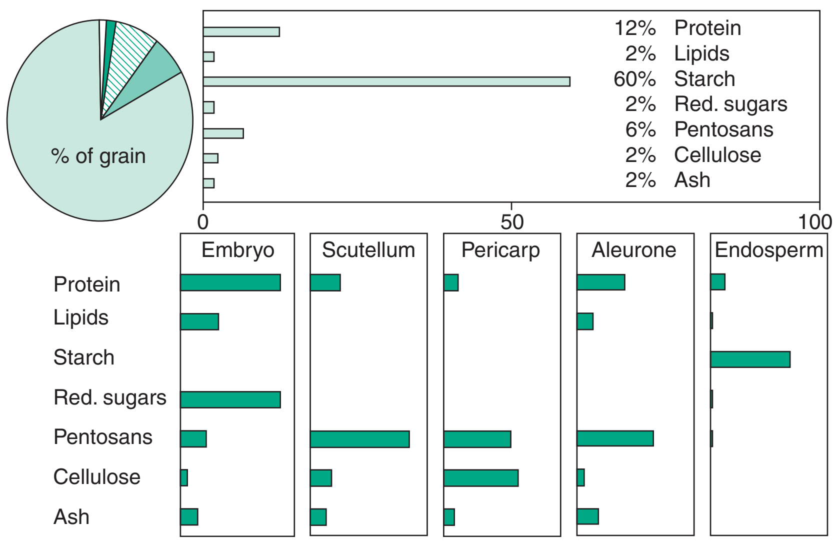

Figure 3 Chemical composition of wheat grain; distribution between anatomical parts. "Red. sugars" means reducing sugars, such as glucose.

Analysis of Protein Content

Today, the routine determination of protein content of all grain species generally involves the use of near infrared (NIR) spectroscopy, applied to whole grain, milled grain, or flour (Table 2). In the case of wheat only, protein content can also be determined by washing out the gluten protein (*see* **Gluten and Modified Gluten**) and weighing its wet mass. Even though gluten protein is less than 80% of the total grain protein, this approach can be used if appropriate correlations are established between the level of washed gluten and "true" grain protein content.

Further possibilities include colorimetric methods (e.g., the biuret reaction) or the amide distillation procedure (Table 2). The standard ("true") method for protein determination involves the complete digestion of the grain or flour to its elements, and determination of the proportion of the element

nitrogen. This figure is multiplied by 6.25 to obtain the protein content, or by a factor of 5.7 in the case of wheat. This procedure assumes that virtually all the nitrogen in the grain is in the form of protein. A lower multiplication factor is used for wheat because its protein contains a high proportion of the amino acid glutamine, giving its protein an unusually high nitrogen content.

The total-nitrogen content is used as an absolute value in establishing correlations for the routine method of NIR spectroscopy to determine the protein content of whole grain or of milled products (Table 2).

Table 2 Methods used to determine the protein content of cereal grain, especially wheat

Process	*Material assayed*	*Assay method*
	Grain	NIR
Mill	Flour/meal	NIR
↓		
Wash (for wheat only)	Gluten	Weight (wet or dry)
↓		
Extract	Protein in solution	Biuret or dye-binding reaction
↓		
Hydrolyze	Amino acids	Gas or liquid chromatography
↓		
Alkaline digestion	Amide N	Titrate ammonia released
↓		
Acid digestion	Ammonia or nitrogen	Kjeldahl or Dumas methods

Protein Quality

The "single figure" of protein content, however, does not take into account the quality of the protein. This quality is indicated for nutritional purposes by analysis of the levels of essential amino acids after hydrolysis of the peptide bonds. For wheat, for example, the quality of the protein relates to the dough strength provided by the particular combination of gluten proteins present, determined partly by the genotype (the variety) and also by the growth conditions.

For the animal-feed industry, the amino-acid composition is especially important, due to the need to ensure an adequate supply of essential amino acids (*see* **Animal Feed**). The protein of cereal grains is a good source of most of the essential amino acids, with the exception of lysine and possibly tryptophan, which are lower in the cereal grains than in most animal proteins. The amino-acid composition for wheat is shown in Figure 4, with respect to the major classes of wheat proteins.

Comparing the Proteins of Cereal Species

The various cereal species differ in the composition of their grain proteins. To a large extent, these differences explain the differences between the cereals with respect to their food uses. The most obvious example is wheat, whose gluten-forming storage protein is unique amongst the cereals in suiting wheat flour for bread making. Furthermore, the proteins of the rice grain contribute to its eating quality. The differences in the protein composition of the

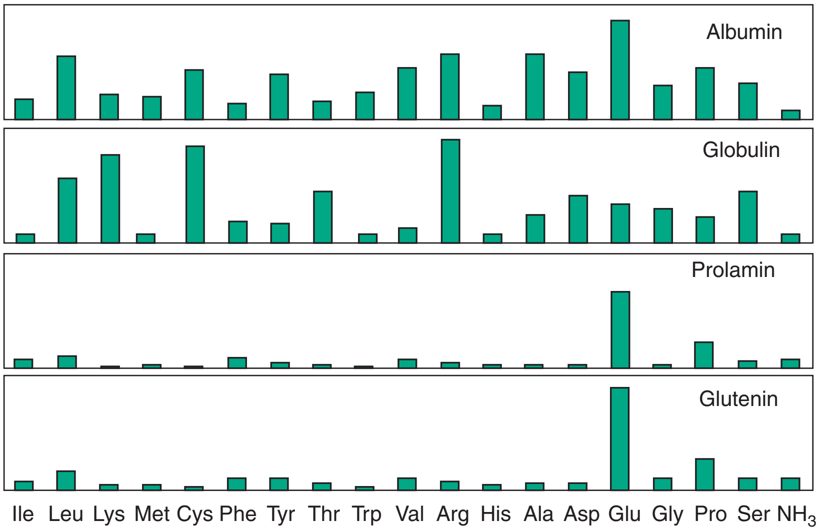

Figure 4 Amino-acid composition of the Osborne fractions of wheat.

cereal grains reflect the taxonomic relationships between them, as is illustrated in Figure 5. The storage proteins of the cereal endosperm are broadly termed "prolamins," with specific names for the prolamin proteins of each cereal genus, as listed in Table 3.

The Proteins of Wheat, Rye, and Triticale

Wheat and rye are closely related, and triticale is a manmade hybrid between wheat and rye (*see* **Taxonomic Classification of Grain Species**). Their protein compositions are thus similar to a limited extent, but the dough-forming quality of rye and triticale is much poorer than that of wheat. The roles of wheat-grain proteins are described in greater detail in relation to wheat quality in **Wheat**: Grain Proteins and Flour Quality.

The popularity of rye-based foods is not so widespread as that of foods made from wheat. Rye is especially popular in eastern European and Scandanavian countries. Baked products are commonly crispbread and varieties of bread, including pumpernickel. Whereas "true" rye bread is made from 100% rye, it is common for rye bread to be made from a blend of rye and wheat flours, the contribution of the wheat gluten being needed to provide the baking quality that is lacking in the rye gluten. The poorer dough-forming characteristics of rye gluten is largely due to the lower level of the glutelin-type protein, combined with the more hydrophilic (water loving) properties of the rye secalins, compared to the corresponding classes of protein in wheat (*see* **Wheat**: Grain Proteins and Flour Quality.

The water-soluble proteins of rye contain the albumin and globulin classes of proteins, similar to those in wheat, but for rye there is generally a higher level of amylase enzymes than in wheat because of the greater susceptibility of rye to preharvest sprouting and the consequent production of starch-degrading enzymes.

The essential amino-acid composition of rye is slightly better than that of wheat, because of the lower content of prolamin-type proteins in rye (Figure 5). The properties of triticale are intermediate between those of rye and wheat, reflecting the genetic origins of triticale.

Table 3 Names for the storage prolamins of the cereal grains

Cereal species (common name)	*Genus name*	*Name of storage prolamin*
Barley	*Hordeum*	Hordein
Maize (corn)	*Zea*	Zein
Oats (as groats)	*Avena*	Avenin
Rice (milled)	*Oryza*	Oryzin
Rye	*Secale*	Secalin
Sorghum	*Sorghum*	Kafirin

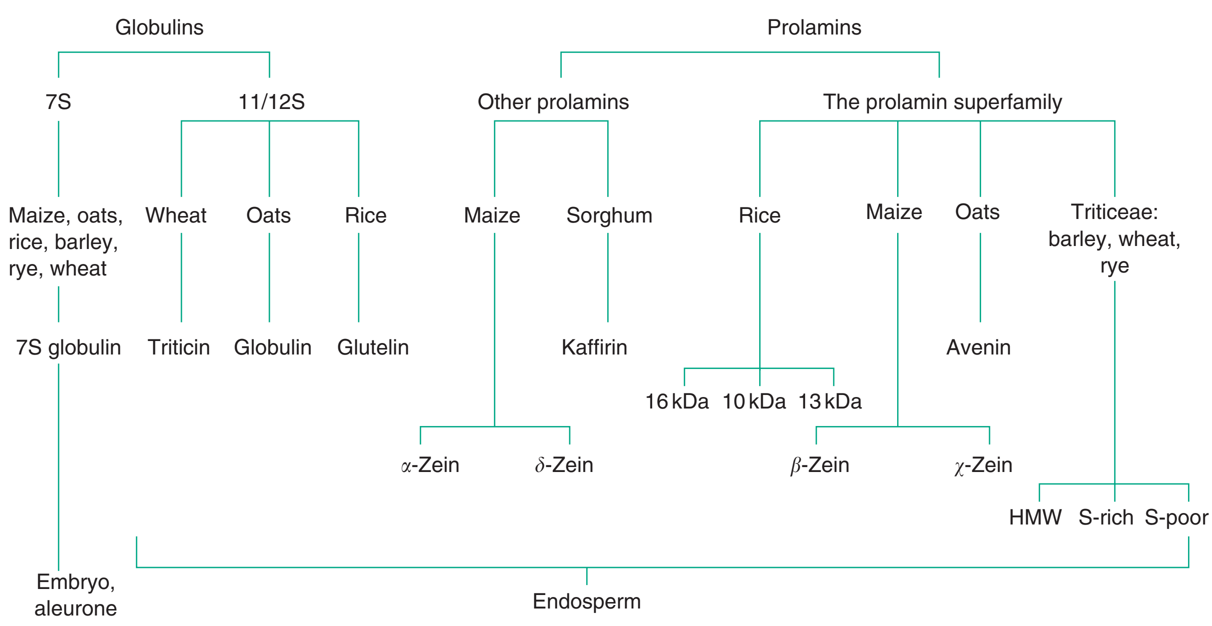

Figure 5 Storage-protein classes in cereals. (Adapted from Shewry PR, Tatham AS, and Halford NG (1999) The prolamins of the Triticeae. In: Shewry PR and Casey R (ed.) *Seed Proteins*, pp. 35–78. The Netherlands: Kluwer Academic.)

The Proteins of the Barley Grain

The protein content of cultivated barley ranges from ~9% to 12%. For barley, the protein content is generally calculated as total nitrogen content multiplied by the factor of 6.25. The protein content of hull-less (naked) barley genotypes is generally higher (up to 18%) because of the absence of the outer layers, which contain relatively little protein (Figure 2). The production of the enzymes of germination is an important part of a good malting barley, but paradoxically, high protein content (e.g., over 11%) is not necessarily desirable for best malting quality. This is because the ultimate test of malting quality is the extent of "extract" produced during the mashing process. The amount of extract determines how much beer can be produced from a given amount of malt. "Extract" represents the amount of soluble fermentable sugars from the hydrolysis of starch, resulting from the combination of very active amylases and high starch content. For this reason, a low protein content (i.e., less than 8%) is also undesirable, as it may have the consequence of inadequate enzyme production.

Consumption for human food is a traditional use of barley, but this now accounts for only ~5% worldwide. Feed use predominates, amounting to ~75% of barley use. The amino-acid composition of barley does not provide a consistently better balance nutritionally than other cereal grains, still being deficient in lysine, methionine, and threonine. Nevertheless, it is a popular source of protein and energy in feedstuffs, in combination with other sources of energy. High lysine barley genotypes have been developed, analogous to those in maize, the first of these being the Hyproly line, screened from the world barley collection. The hordein polypeptides show considerable polymorphism, like the prolamins of wheat and rye. A large proportion of the barley prolamins are disulfide linked with naturally occurring polymers of high molecular weight. Unlike the glutenin polymers of wheat, these are not desirable for the processing of barley. Because they generate problems in the malting process and downstream, they are likely to produce haze in the final product, i.e., (beer) if they have not been adequately hydrolyzed during processing.

The hordein polypeptides are classified into groups (A, B, C, and D hordeins) according to their decreasing mobilities during SDS gel electrophoresis. The C hordeins have analogy to the omega-gliadins of wheat, having a general absence of the sulfur-containing amino acids. They are coded by genes (locus *Hor 1*) on the short arm of barley chromosome 1H, as indicated in Table 4. The genes (*Hor2* and *5*) for the sulfur-rich B and gamma hordeins are also coded on chromosome 1H. The D hordeins, which occur as disulfide-linked polymers, are analogous to the high-molecular-weight subunits of wheat glutenin; like them, their genes (*Hor 3*) are located on the long arm of the corresponding barley chromosome (1H).

Table 4 Classes of barley proteins (hordeins) and corresponding loci

Hordein class	*Loci*	*Gene copy number*	*Proteins present in cv. Carlsberg.*	*MW (kDa)*	*Corresponding wheat prolamin*
B	*Hor2*	20–30	10	36–45	LMW glutenins
C	*Hor1*	20–30	9	50–60	ω-Gliadins
D	*Hor3*	1	1	105	HMW glutenins
γ	*Hor5*	Low	7	36–45	γ-Gliadins

The Proteins of the Rice Grain

The proteins of rice are a contrast to those of wheat and barley, because the rice-grain proteins are predominantly of the globulin class. As a protein source, milled rice contains the lowest amount of protein (~5%) among the major cereals. Moreover, this protein is not easily digestible by human and monogastric animals. However, compared to that of other cereal proteins, the overall amino-acid composition of rice protein is significantly more balanced due to the relatively higher level of lysine content. This unusual amino-acid composition results because rice is one of the few cultivated plants in which there are significant levels of globulins and prolamins. These are the two major classes of storage proteins in the seeds of higher plants. Unlike other cereals that accumulate prolamins as their primary nitrogen reserve, the major storage proteins in rice are the glutelins, which are homologous at the primary sequence level to the 11S globulin proteins (Figure 5), a class that is the dominant form of nitrogen deposition in legumes. Rice prolamin proteins have a number of characteristics that are different from the prolamins present in most other cereals (*see* **Wheat**: Grain proteins and Flour quality).

The most important characteristic of the deposition of nitrogen in the rice kernel is that there are three kinds of protein bodies in the rice endosperm, namely, large spherical, small spherical, and crystalline protein bodies. Each of these is surrounded by a single continuous membrane. Although the spherical protein bodies form within vacuoles, the proteins are synthesized in the endoplasmic reticulum and in the Golgi apparatus, and are then transported to the

vacuoles via vesicles. Removal of the husk (hull) from rough (paddy) rice yields the kernel. This is composed of the pericarp, seedcoat, aleurone, endosperm, and the germ, and is known as "brown rice." It has a protein content of ~9–10%, with a significantly higher nutritional value than the most commonly utilized rice product – white polished (milled) rice, whose protein content is ~8%.

The milling process for paddy rice results in 40–55% white milled rice, together with three major by-products, namely, husks (20%), bran (10%), and brokens (10–22%). These by-products have protein contents of 3%, 17%, and 9%, respectively. The aleurone layer, the tissue with the highest level of proteins and nutritionally important minor components, is removed during the rice-milling process.

The subaleurone region of the rice grain plays an important part because of its nutritional value. It is a globulin-rich layer, being several cell layers thick. Its lysine content is much higher than that of the proteins located in the rice endosperm. Thus, rice should be milled as lightly as possible to retain as much as possible of the subaleurone layer.

The albumin fraction of rice is highly heterogeneous, containing biologically important components. It can be separated into four subfractions, based on the molecular size of its proteins. More than 50 individual polypeptides were observed in the albumin fraction, using isoelectric focusing. As for cereal grains in general, the albumins are mainly enzymes and enzyme inhibitors.

Like the prolamins from other cereals, rice prolamins are readily soluble only in alcohol/water mixtures. However, the classical extraction procedure had not been useful in early studies. More recently, these estimates of prolamin content have been shown to be low. Using 55% propan-l-ol and reducing agents, higher yields of prolamins (20–25% of the total protein) have been obtained. Rice prolamins are ~10–16 kDa. Thus, their molecular size range is significantly smaller than the prolamins from other cereals. They are highly variable between rice cultivars, based on their electrophoretic and isoelectric focusing fingerprints.

According to the Osborne classification system, the glutelins comprise the major protein fraction of the rice grain, representing up to 80% of the total protein fraction (Figure 5). The rice glutelins have been difficult to study because of their general insolubility in all solvents except dilute alkali, due to their high molecular weight and their heterogeneity. When analyzed by gel filtration chromatography, the purified glutelin fractions were resolved into three subunits, linked by disulfide bonds, which varied in stoichiometry depending on the report and on the rice variety used.

When subjected to cation-exchange chromatography, the glutelins separate into a heterogeneous set of acidic and basic subunits. The acidic subunits are 28.5–30.8 kDa in size, with pIs between 6.5 and 7.5, while the basic subunits are smaller (20.6–21.6 kDa) with pIs from 9.4 to 10.3. The acidic subunits contain nearly twice as much glutamic acid/glutamine and more serine and glycine, whereas the basic subunits contain more alanine, lysine, aspartic acid/asparagine, and isoleucine.

Despite their general insolubility, rice glutelins are homologous in structure to 11S globulins (Figure 5). The structural relationship is evident when comparing the N-terminal amino-acid sequences and by using immunological methods. The extent of homology between the rice glutelin and legume 11S globulins is ~30–35%. Structural similarity is evident in the primary sequences of homology to a motif common in wheat, rye, barley, and maize prolamins.

The Proteins of Maize

Maize (or corn), often classed in world trade as one of the "coarse" grains (*see* **Cereals**: Overview), is an important source of protein in the diets of many people in countries such as Africa and South America (*see* **Grain Production and Consumption**: Africa; South America). In addition, maize is used extensively as a feed grain and in a range of industrial processes (*see* **Maize**: Dry Milling; Wet Milling; Foods from Maize). The process of cornstarch manufacture produces the grain protein as a by-product. It is sometimes referred to as "corn gluten" in the trade, but this name is inappropriate, because maize protein has no relationship to the gluten of wheat (*see* **Nutrition**: Beriberi, A Deficiency Related to Grains and **Celiac Disease**).

Like the other cereal grains, maize protein is slightly deficient in lysine. This limits its utilization as an animal feed. This nutritional imbalance is largely due to the low lysine content of "zein," the major group of maize proteins (Figure 5). The development of the "opaque-2" and "floury-2" mutations has led to the development of maize genotypes with higher levels of lysine, due to a lower content of zein and more of the nutritionally superior albumin type of protein. Although these new maize types offer nutritional advantages, they carry a yield penalty.

The zein protein of maize can be isolated by extraction of the crushed endosperm (the starchy part of the grain) with 70% aqueous ethanol, after breaking disulfide bonds. Maize zein has been further fractionated into subclasses of proteins, designated alpha-, beta-, gamma-, and delta-zeins. The genes

for their synthesis have been mapped to maize chromosomes 6 and 7 (*see* **Maize**: Genetics).

The Proteins of Sorghum

The major storage proteins of sorghum, termed "kafirins" (**Figure 5**), are fractionated by a procedure similar to that for the zeins of maize. Alpha-kafirin, comprising ~80% of the overall kafirin content, can be further subdivided into two proteins with molecular weights of ~23 and 25 kDa. Three beta-kafirins and one gamma-kafirin have been identified, all of them having molecular weights in the range 16–28 kDa. Like maize, high lysine mutants of sorghum have been developed.

Future Prospects

Recent decades have seen enormous increases in the understanding of the chemical and functional properties of the cereal proteins, permitting more efficient selection for improved processing quality in the breeding of new varieties. This knowledge is also being applied to testing for protein quality after the grain is harvested, so that grains of specific quality can be segregated for appropriate marketing and processing. Knowledge at the chemical level is now complementing new genetic insights, so that breeders and molecular geneticists can employ conventional and novel methods to create quality types that have previously not been possible – varieties with new protein functionality – so that the future holds great promise for grains that will be processed more efficiently with nutritional advantages.

Evolution of Species

L A Morrison, Oregon State University, Corvallis, OR, USA

Introduction

Cereals comprise a diverse collection of species, all belonging to the grass family (Poaceae). As a group, they are named for the Roman goddess Ceres who, along with her Greek counterpart Demeter, was worshipped as the mother of agriculture. Among Ceres' symbols were spikes of wheat and thus her designation as goddess of grain. Cereal evolution is

a complex subject given the vast array of species adopted into agriculture by cultures across five continents. Most researchers and consumers think in terms of a relatively narrow selection of cereal species that now dominate international commerce as dietary staples or constituents in processed food products. In this select group are barley, maize, millet, oat, rice, rye, sorghum, and wheat. In actuality, cereals comprise a much larger group with many lesser-known species that serve as dietary staples on a local basis, particularly in subsistence farming cultures.

Reproductive Biology

Members of the grass family all have inconspicuous flowers that have been reduced to the essential reproductive structures. There are no showy bracts, nectaries, and other features to attract pollinators, for these species rely on wind pollination to distribute their pollen. Although grass flowers all have the same basic design (**Figure 1**), there is variation in the development of the female and male reproductive structures in terms of their presence or functionality. The flower, when perfect, contains three or six *stamens*, one *pistil*, and two *lodicules*, which are scale-like appendages positioned on either side of the ovary base. Enclosed by two outer leaf-like bracts (*lemma* and *palea*), these structures form a floral unit or *floret* (**Figure 1**). The floret is attached to a stem axis, the *rachilla*. Subtending the rachilla are two empty bracts, the *glumes*. One or more florets, packaged within the glumes, form a *spikelet* (**Figure 1**). Spikelets are alternately positioned at attachment points (*nodes*) located along a main inflorescence axis (*rachis*) or on branches extending off the rachis. The interval between two nodes on the rachis is the *internode*. Within the spikelets, florets are similarly arranged, alternately along a secondary axis (*rachilla*). Although

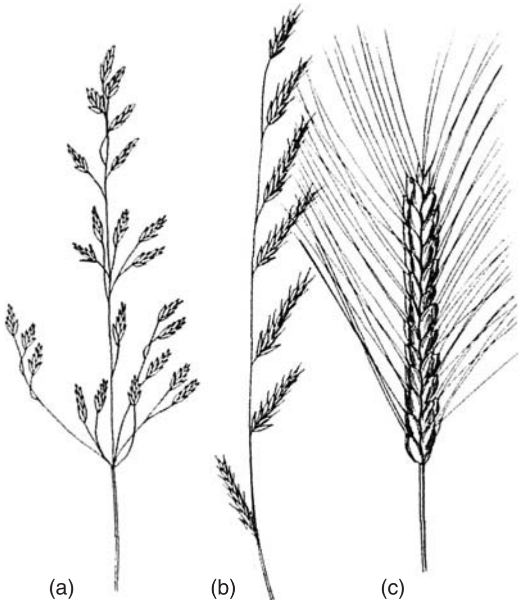

Figure 2 Illustrations of the three general inflorescence types found in grasses: (a) panicle, (b) raceme, and (c) spike. (Reproduced with permission from Clark LG and Pohl RW (1996) Agnes Chase's *First Book of Grasses*. Smithsonian Press.)

inflorescence morphology is very complex, a simplistic classification designates three basic inflorescence types (Figure 2), each differing in branch development and spikelet attachment: (1) *panicle* with long, open branches (rice) or short, dense branches (pearl millet), each bearing a pediceled spikelet; (2) *raceme* with spikelets borne on short pedicels along the rachis (barley); and (3) *spike* with spikelets sessile along the rachis (wheat).

Pollination and Fertilization

Cereal species can be either self- or cross-pollinating. Wind and air currents serve as the mechanism by which the pollen of cross-pollinating cereals is distributed. In cross-pollinating species, the functional role of the lodicules is evident at anthesis when they swell, forcing open the florets to expose the stigmatic surfaces and allowing the anthers to shed their pollen into the air. Elongation of the stem-like filaments on the stamens pushes the anthers upwards and out of the floret. The glumes can bend outward at their bases, allowing more room for the florets to open. For self-pollinating cereal species whose florets do not stay tightly closed at anthesis, cross-pollination can occur at low levels. Given the hybrid speciation events that have shaped the formation of polyploid species such as oats and wheat, it is clear that the functional morphology of the floret and spikelet serves an important role in cereal evolution.

The stigma, a collection of sticky feather-like branches, serves as the pollen trap (Figure 1). Upon pollination, a pollen tube grows downward through the stigma and style into the ovary which holds a single ovule. Fertilization occurs when the pollen sperm nuclei unite with the egg and two female polar nuclei. From this event, a grain develops with a $2n$ embryo and $3n$ endosperm. When fully developed, the cereal grain is the fruit and seed combined, i.e., a specialized fruit known as a caryopsis, whose outermost layer is the dried remains of the ovary (*pericarp*) now adherent to the seed within. In wild grass species, the mature caryopsis can be protected within a hardened, shell-like package formed by the lemma and palea or encased as one of several caryopses within a spikelet unit formed by tough, tightly clasping glumes. Another means of protection are adherent lemmas and paleas, which, while not forming a hardened barrier, do serve a protective function. These wild-type strategies serve to protect the caryopsis during dispersal and early seedling establishment. In domesticated cereals, the protective features of the bracts have been lost or, to some extent, reduced. Cereals with naked grains have lost all the protective features of the lemmas, paleas, and glumes.

Dispersal

In wild grasses, survival depends upon natural dispersal strategies that move the mature grain off the mother plant and spread it to new habitats, expanding opportunities for success into the next generation. By contrast, the domesticated cereal grain is retained on the plant rather than dispersed and in many cases, no longer protected by the bracts. As a consequence, it is dependent upon humans to move it away from the mother plant (i.e., to disperse the grain) and to protect it from predation and environmental threats. These different strategies illustrate variations on the evolutionary theme of dispersal. Cereal researchers often overlook the connection between the wild dispersal mechanisms and the domesticated traits of grain retention on the plant and grain release from the bracts during threshing. With respect to the latter, free-threshing grains are those, like wheat, which can be easily freed from the brittle glumes, lemma, and palea by threshing action.

Dispersal units (*diaspore*) are created by a spontaneous shattering (*disarticulation*) in abscission zones located at the nodal points along the rachis or rachilla (Figure 3). Disarticulation is typically described as above (rachilla disarticulates into floret units) or below the glumes (rachis disarticulates into spikelet, branch, or inflorescence units). The rachilla

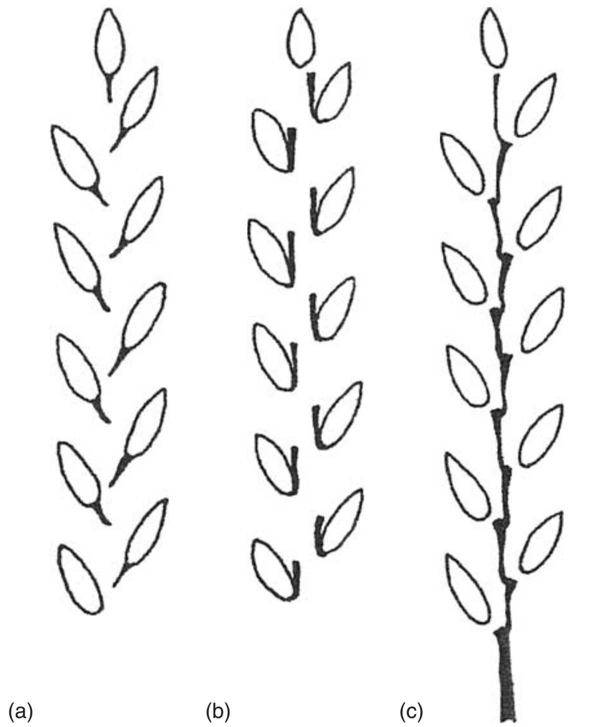

Figure 3 Disarticulation points along the rachis illustrating the location of the break and the internode piece attached to the diaspore: (a) arrow-shaped diaspore with subtending rachis piece; (b) cylindrical diaspore with adjacent rachis (rachilla) piece; (c) tough rachis with no disarticulation. Disarticulation points along the rachilla follow the same pattern illustrated in (a) and (b). (Reproduced with permission from Peterson RF (1965) Wheat: botany, cultivation, and utilization. In: Polunin N (ed.) *World Crop Books*. New York: Interscience.)

and rachis internodal pieces that remain attached may either subtend or lie adjacent to the diaspore (Figures 1 and 3). Rudimentary or sterile inflorescence structures may also form part of the diaspore as is the case with the two sterile awn-like lateral spikelets on the wild barley diaspore and the reduced inflorescence branches that form a bristly fascicle on the wild pearl millet diaspore.

In some species, toughened glumes completely enclose the spikelet in a protective package that secures the grain from predation and environmental damage (wild wheat). In other species, the lemma and palea adhere to the grain (wild barley) or form a hard shell around the grain (wild pearl millet). Shape and awning of the diaspore determines its mode of movement once reaching the ground. For example, cylindrically shaped diaspores move by rolling on the ground, floating on water, or getting caught in mud that sticks to the hides or in the hooves of animals (wild wheat); arrow-shaped units fall or are moved point downward into soil cracks (wild rye). Awns, which are extensions of the vascular nerves of glumes and lemmas, can move the diaspore downward into the soil in several ways. Long, straight awns vibrate in the wind to push the diaspore downward (wild wheat). Hygroscopic awns twist in response to moisture changes, thereby drilling the diaspore into the ground (wild oat). Awns and bristles also function to move dispersal units away from the mother plant to a new site. Tiny barbs on awns can attach the diaspore to the fur of animals or clothing of humans (wild wheat and barley). Lightweight, feathery bristles can move a diaspore in the wind (wild pearl millet).

Evolution and Domestication

Acting as evolutionary selection agents, early humans channeled the inherent genetic variation of wild grasses in the direction of agricultural traits that eased work to cultivate, harvest, and extricate grain. Domesticated cereals have continued to intercross with their wild progenitors and relatives, with the result of blurred boundaries between wild and domesticated species. As a consequence of the variation that has developed under human hands and the intermixing of wild and domesticated forms, cereals are problematic in their taxonomy and phylogenetic treatment (*see* **Taxonomic Classification of Grain Species**). Alternative generic and species concepts abound in cereal species taxonomy. They reflect divisions within the research community as how to best interpret the relationship between wild and domesticated forms and how to categorize the extensive phenotypic, yet minor genetic, variation within a given cereal species. Often missing from these debates is the recognition that domestication is representative of the larger process of evolutionary change and speciation.

Wild Progenitors and Weedy Species

Wild progenitors of domesticated cereals are often species that adapted well to human-made habitats, i.e., they prospered in the disturbed environments created by human activities and proved amenable to cultivation. With domestication, these habitats expanded to agricultural fields where wild progenitors or their close relative species often became weeds. When domesticated forms and their wild, weedy progenitors hybridized, crop–weed complexes developed, and continue to develop. For these species, the line between the domesticated form and its wild relatives is not always well drawn. On the other hand, the resultant gene flow has played a significant role in shaping their genetic variation. Development of weed races is the natural consequence of the interdependent evolutionary relationship between humans and the wild grasses that they domesticated.

While a nuisance in crop fields that they infest, weedy cereal species are simply plants responding to the selection pressures set up by an agricultural system.

Traits of Domestication

Under domestication, features of dispersal, reproduction, plant growth, and survival of wild grasses were transformed into desirable agricultural traits for improved cultivation and grain yield. Among the more critical transitions were: (1) suppression of dispersal mechanisms; (2) reduction of seed dormancy either by loss of physiological dormancy or by loss or reduction of enclosing bracts that contained germination inhibitors; (3) increase in seed production by development of reproductively functional florets and spikelets from sterile or reduced inflorescence structures; (4) increase in seed size; (5) synchronous development of tillers and ripening of the grain; and (6) greater agricultural fitness for soil and climatic conditions and pest resistance.

While all of these traits have played significant roles in domestication, the transition of dispersal traits is the critical event by which the effort expended on gathering and processing grains was made easier. Development of a tough, non-disarticulating rachis enabled humans to harvest mature inflorescences directly from the plant. Reduction or loss of tough, tightly clasping bracts led to free-threshing cereals. In a separate evolutionary development, loss of adherent lemmas and paleas produced a naked grain easily released in threshing. The term *hulled* cereal collectively refers to different protective features of the bracts in domesticated cereals that have not completely lost wild-type features. A *hulled grain* is one that is either encased within the lemma and palea, which either form a hard shell around the grain (pearl millet) or are adherent to the grain surface (barley). A *hulled spikelet* has hardened, tough glumes that tightly enclose one or more grains in a spikelet package (spelt wheat).

Major Cereal Species

Major cereal species (Table 1) are those that are either in international commerce or serve as a dietary staple beyond a localized region. Wheat and barley are temperate cereal crops of the Fertile Crescent and along with oats and rye formed the major grain complex for Western Asia, North Africa, and Europe. Maize and rice are the tropical cereals upon which civilizations in the New World and Eastern Asia developed. Although sorghum, millet, and African rice, all tropical African species, have historically been given a lesser role, they are equally important in the establishment of early human civilizations in Africa and South Asia.

Barley

Barley was domesticated along with wheat as one of the founder crops of Old World Neolithic agriculture. Unlike the wheats, barley consists of only one domesticated diploid species (*Hordeum vulgare*) and its wild relative counterpart (*H. spontaneum*), which is found in both wild and weedy forms (*see* **Barley**: Genetics and Breeding). Although barley has a lengthy agricultural history and development of an extensive

Table 1 Major cereals and their wild and weedy relatives

Common name	*Domesticated species*	*Wild progenitor species*	*Weed race*	*Region of domestication*	*Date of domestication*[a]
Barley	*Hordeum vulgare*	*H. spontaneum*	*H. spontaneum*	West Asia	9500–8400 BP
Common oat	*Avena sativa*	*A. fatua* *A. sterilis*	*A. fatua* *A. sterilis*	Europe	4000–3000 BP
Maize	*Zea mays*	*Z. mays* (teosinte) *Tripsacum dactyloides*	*Z. mays* (teosinte)	MesoAmerica	7000 BP

Rice	*Oryza sativa*	*O. rufipogon* *O. nivara*	*O. sativa* f. *spontanea* *(O. fatua)*	Southeast Asia	5500–4000 BP
Rye	*Secale cereale*	*S. montanum* (= *S. strictum*)	*S. cereale* ssp. *ancestrale* ssp. *dighoricum* ssp. *segetale* ssp. *afghanicum*	West Asia	4000 BP
Sorghum	*Sorghum bicolor*	*S. arundinaceum*	*S. halepense* (4×)	Central Africa	2000 BP[b]
Bread wheat	*Triticum aestivum*	unknown	*Aegilops* spp.	Central Asia	8000–7000 BP
Durum wheat	*Triticum durum*	*T. dicoccoides*	*Aegilops* spp.	Western Asia	9000–8000 BP[c]

[a] Based on reports in the current literature dealing with the archeological record, approximate date of known cultivation of the domesticated species.
[b] Early archeological sites in Africa are unknown. These dates reflect sorghum's later movement into India.
[c] Dates represent first appearance of free-threshing tetraploid wheats in the archeological record.

number of cultivars and land races, its morphological diversity is relatively limited. Its unique feature is the presence of three spikelets at each rachis node. Development of these spikelets forms the basis for dividing barley into two groups: (1) two-rowed barley with only the central spikelet fertile (primitive form) and (2) six-rowed barley with all three spikelets fertile (advanced form). Most domesticated barley has a hulled grain, although there are naked six-rowed cultivars given the botanical ranking of var. *nudum* (= var. *coeleste*). A fragile-rachis, six-rowed domesticated barley discovered in Tibet was originally proposed as a distinct wild, progenitor species and named *H. agriocrithon*. It has proven to be an introgressed form arising from hybridization between domesticated barley and weedy forms of *H. spontaneum*.

Maize

Among the domesticated cereals, maize (*Zea mays*) is unusual as a monoecious species whose cob, a highly compressed female raceme, bears naked grains. Wild maize relatives include various infraspecific forms of *Z. mays* and other wild and weedy annual and perennial *Zea* species (teosinte) and gamagrass, a member of the closely related genus *Tripsacum*. Theories explaining maize evolution have had to contend both with the absence of an identifiable wild progenitor as well as provide an explanation for the development of the highly specialized female inflorescence. Although researchers generally agree that maize evolved from teosinte, there is no universal agreement for explaining the steps from wild to domesticated forms. Current theories explaining maize evolution include the following: (1) a gradual change toward the domesticated form by mutation; (2) feminization of male flowers by a catastrophic mutation event, (3) rapid change by human selection of maize-like mutants, and (4) human selection of teosinte × *Tripsacum* hybrids (*see* **Maize**: Genetics).

The possibility of a teosinte × *Tripsacum* hybrid was originally proposed as the "tripartate hypothesis" whereby teosinte evolved from hybridizations between a maize progenitor, identified from the archeological record as pod corn, and a *Tripsacum* species. A more recently proposed scenario suggests human selection of maize-like forms that originated from natural hybridization between teosinte and *Tripsacum* and subsequent introgression. This hypothesis is supported by experimental hybridizations and offers the advantage of tying together biological and archeological evidence. Whatever the final elucidation of the evolutionary steps leading to maize, the role of humans in promoting the conditions by which speciation events (e.g., creating hybrid habitats) occurred is as equally important as was their role as selection agents in directing the naturally occurring variation toward domesticated maize.

Millet

Millet in a broad sense actually comprises a loose grouping of small-seeded, drought-tolerant species that can be cultivated on poor soils (Figure 4). They belong to nine genera in the grass subfamilies: Paniceae (eight genera) and Chloridoideae (one genus) (Table 2). Due to a small size and hardened lemma and palea, millet grains are insect resistant, a feature that adds to their value for the African and Asian cultures that cultivate them. Only pearl millet (*Pennisetum glaucum*) is a major cereal grain on an international scale (*see* **Millet**: Minor). It was domesticated in tropical West Africa and still forms an integral component of décrue (flood stage to dry) agriculture in the Central African river deltas where it is cultivated along with African rice (*Oryza glaberrima*) and sorghum (*Sorghum bicolor*). Low genetic variation suggests a relatively limited region of origin, although the diversity of morphological forms has led to the classification of as many as 18 domesticated species (*see* **Millet**: Pearl). Pearl millet is a largely cross-pollinating species due to the unsynchronized maturity of the respective female and male flower structures. Although originally native to West Africa, pearl millet spread into India in prehistoric times where it became a major food staple. Active introgression makes it difficult to draw clear phylogenetic lines between pearl millet, its wild progenitor *P. violaceum*,

Yellow foxtail	*Setaria glaucum*	India	Domesticated
Foxtail millet	*Setaria italica*	China, Europe	Domesticated
Oats	*Avena*		
Abyssinian oat	*A. abyssinica*	East Africa	Wild
Sand oat	*A. hispanica*	Spain	Domesticated
Rice			
Wild rice	*Oryza barthii*	West Africa	Wild
African rice	*Oryza glaberrima*	West Africa	Domesticated
Southern wild rice	*Zizania aquatica*	North America	Wild
Northern wild rice	*Zizania palustris*	North America	Wild, domesticated
Sand Bur	*Cenchrus biflorus*	Central Asia	Wild
Tef	*Eragrostis tef*	Ethiopia	Domesticated
Wheat ($2\times$)	*Triticum*		
Small spelt	*T. monococcum*	Eurasia	Domesticated
Wheat ($4\times$)	*Triticum*		
Emmer	*T. dicoccum*	Eurasia	Domesticated
Isphahan wheat	*T. ispahanicum*	Iran	Domesticated
Georgian emmer	*T. paleocolchicum*	Georgia	Domesticated
Ethiopian wheat	*T. aethiopicum*	Ethiopia	Domesticated
Khorasan wheat	*T. turanicum*	Iran	Domesticated
Persian wheat	*T. carthlicum*	Southwest Asia	Domesticated
Polish wheat	*T. polonicum*	Southwest Asia, Mediterranean Basin	Domesticated
Poulard wheat	*T. turgidum*	Eurasia	Domesticated
Timopheev's wheat	*T. timopheevii*	West Asia	Domesticated
Wheat ($6\times$)	*Triticum*		
Spelt wheat	*T. spelta*	Eurasia	Domesticated
Macha wheat	*T. macha*	Georgia	Domesticated
Vavilov's wheat	*T. vavilovii*	Georgia	Domesticated
Shot wheat	*T. sphaerococcum*	India	Domesticated
Zhukovsky's wheat	*T. zhukovskyi*	Georgia	Domesticated

[a] Wild species are undomesticated and are weedy species that usually inhabit disturbed sites or agricultural fields. Some domesticated species listed here are recognized in other regions.
[b] Member of the subfamily Chloridoideae. All other millet species belong to the subfamily Paniceae.

and the weed species *P. sieberianum*. Crop mimicry is a problem in African fields of pearl millet where weed races of *P. sieberianum*, known as shibras, are almost indistinguishable from the domesticated species.

Oats and Rye

Common oat (*Avena sativa*) and rye (*Secale cereale*) developed as secondary cereal crops, beginning their

evolutionary routes toward domestication as weeds of wheat and barley fields. The early diploid progenitor species of *A. sativa*, a hexaploid, are unknown. The two weedy hexaploid species, *A. sterilis* and *A. fatua*, are considered to be the immediate wild ancestors, with *A. sterilis* believed to have played the principal role (*see* **Oats**). Differentiated by their disarticulation from the mature panicle, the *A. sterilis* form breaks as spikelet dispersal units containing all florets, whereas the *A. fatua* form disarticulates as individual floret units. According to current theories, oats were domesticated in Europe after they arrived there as weed contaminants in emmer, a primitive tetraploid wheat species (Table 2). Common oat has two hulled-grain types grouped by the location of the rachilla break (Figures 1 and 3) during threshing: (1) *sativa* form (*sensu stricto*) with the rachilla piece attached adjacent to the floret and (2) *byzantina* form with the rachilla piece attached below the floret. The naked-grain common oat cultivars are found in the *byzantina* group.

Rye is a complex of wild, weedy, and domesticated forms classified as *S. cereale*. The weedy rye forms that first infested wheat and barley fields in Western Asia are believed to have evolved from the perennial species *S. montanum*. Intermediate forms derived from hybridizations among the wild *S. montanum* and weedy and domesticated forms of *S. cereale* complicate the taxonomy. The weed races – *segetale*, *afghanicum*, *dighoricum*, and *ancestrale* – from which the domesticated form evolved are included in the *S. cereale* group (*see* **Rye**). This conspecific group includes non-shattering or semi-shattering forms with regional distributions across Western and Central Asia. A true wild race, *vavilovii*, whose spikes disarticulate, is presumed to have evolved from *S. montanum*. Although interfertile with domesticated rye, it is not believed to be a direct progenitor. Rye is a free-threshing, naked-grain species.

Rice

Although there are two species of rice, only one of these, *Oryza sativa*, which evolved in tropical Asia, has become a major cereal staple in international agriculture. In contrast, *O. glaberrima* is a relatively minor rice whose cultivation is confined to the equatorial belt of Western Africa where it is native. Both domesticated species and their wild relatives are diploid. Their high chromosome number ($2n = 24$) suggests that they may be evolutionarily derived from ancient polyploid species whose genomes became diploidized. Both species are semiaquatic plants whose premodern cultivation was tied to seasonal flooding and rains. Of the two, *O. sativa* has a greater climatic and latitudinal diversity with a range of forms found from tropical to temperate zones and cultivable in semiaquatic (lowland rice) versus dry land conditions (upland rice). It is a highly diverse species with three major races – the tropical races indica and javanica, and the temperate race japonica – each with a correspondingly wide range of cultivar diversity. The javanica race may be a derivative of hybridization between indica and japonica cultivars.

Most experts agree that *O. sativa* was domesticated in independent events in South and Southeast Asia. The wild progenitor species *O. rufipogon* is a perennial and it is likely that the steps toward domestication actually began with the annual derivative species, *O. nivara* (*see* **Rice**: Genetics). A weed race of intergrading forms, designated as *O. sativa* f. *spontanea* (= *O. fatua*), has developed from hybridization between domesticated rice and its wild and weedy relatives. The story with *O. glaberrima* is similar. Its direct wild progenitor is the wild annual species, *O. barthii*, which evolved from the perennial species, *O. longistimata*. *Oryza barthii* populates savanna water holes and has weedy forms that infest rice fields located in the high rainfall belt of the African savannah. For both rice species, genetic and morphological differences are sufficiently blurred as a consequence of introgression between the wild and domesticated taxa to prevent any well-defined phylogenetic distinctions.

Sorghum

Sorghum (*S. bicolor*) constitutes a polymorphic species complex of taxa evolved from introgression between domesticated, wild, and weedy forms (*see* **Sorghum**: Breeding and Agronomy). Knowledge of sorghum's domestication history is limited due to the poor archeological record for sub-Saharan Africa. Although the oldest archeological finds are from sites in India, they are interpreted as representing previously domesticated African sorghums brought to the Indian subcontinent by early human migrations. Five sorghum races – bicolor, guinea, durra, caudatum, and kafir – are identified, each with a distinctive eco-geographic range and place in indigenous African and Asian agriculture as well as morphological and use differences (Figure 5). Bicolor is the first evolved race, and along with the durra and kafir races form the stocks from which modern Western sorghum cultivars are developed. Relationships among the various infraspecific forms of sorghum are complicated due to active introgression between and among the domesticated and weed races. Four types of weed races form the sorghum crop–weed complex, each illustrating a different evolutionary route to weed status: (1) weedy wild race, (2) weedy hybrid form

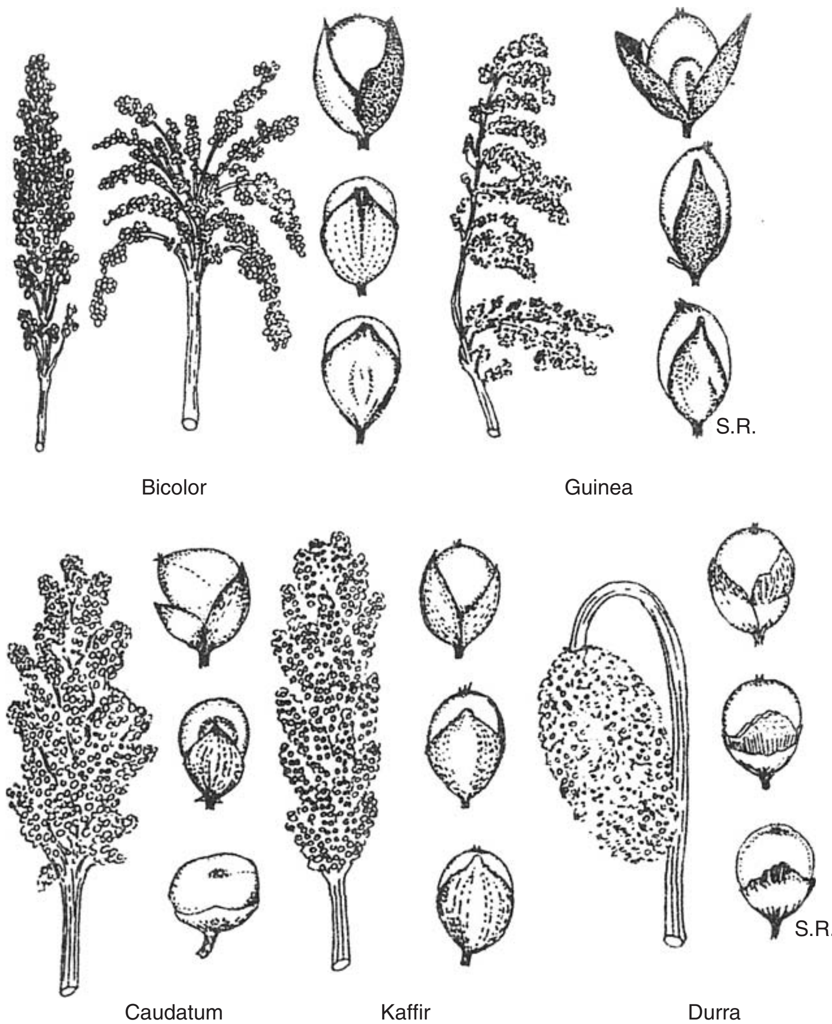

Figure 5 Panicles and mature grains still enclosed within their glumes for each of the five sorghum races. (Reproduced with permission from Luven P (1988) *Traditional Food Plants*. FAO Food and Nutrition Paper 42. FAO.)

derived from a cross of domesticated sorghum × wild sorghum, (3) weedy domesticated forms with a secondary shattering trait, and (4) weedy hybrid forms derived by crosses between domesticated forms. Sorghum also hybridizes with the wild, perennial Asian species, *S. propinquum*, and is believed to be one of the hybrid parents of *S. halepense*, whose weedy form is known as Johnson grass.

Wheat

The wheats comprise a large polyploid complex of wild and domesticated species belonging to the genera *Triticum* (wild and domesticated) and *Aegilops* (wild). For the domesticated species, two distinct evolutionary lines trace to the wild diploid species *T. urartu* and *T. boeoticum*, whose respective genomes are designated as "A," a cause for considerable confusion when not distinguished as either A^u or A^b (*see* **Wheat**: Genetics). The two major wheats – *T. durum* (macaroni wheat) and *T. aestivum* (bread wheat) – are in the A^u-genome line. Primitive tetraploid wheat (A^uB-genomes) evolved directly from the wild tetraploid species *T. dicoccoides*, a derivative of a hybridization between *T. urartu* and a species as yet not definitively identified, but likely *Ae. speltoides* (B-genome). First domesticated in Western Asia, tetraploid wheats (Figure 6) spread inland to Central Asia, westward across Europe, and southward to Northern Africa, differentiating into a diverse array of minor cereals unique for their regional distribution and morphological and agronomic features (Table 2). The hexaploid group, which includes *T. aestivum* (A^uBD-genomes) and several minor hulled and free-threshing forms (Figure 6 and Table 2), has no known wild progenitor. It is believed to have evolved in the continental regions of Central Asia as a consequence of a hybrid speciation event between a domesticated

Figure 6 Diversity within the wheats. From left to right: *T. monococcum*, *T. dicoccum*, and *T. spelta* (all hulled wheats), *T. polonicum*, *T. turgidum*, *T. aestivum* (compactum form), *T. durum*, *T. aestivum* (awned: "Turkey"), and *T. aestivum* (awnless: "Wilhelmina"). (Adapted from The Field Museum, negative B79676.)

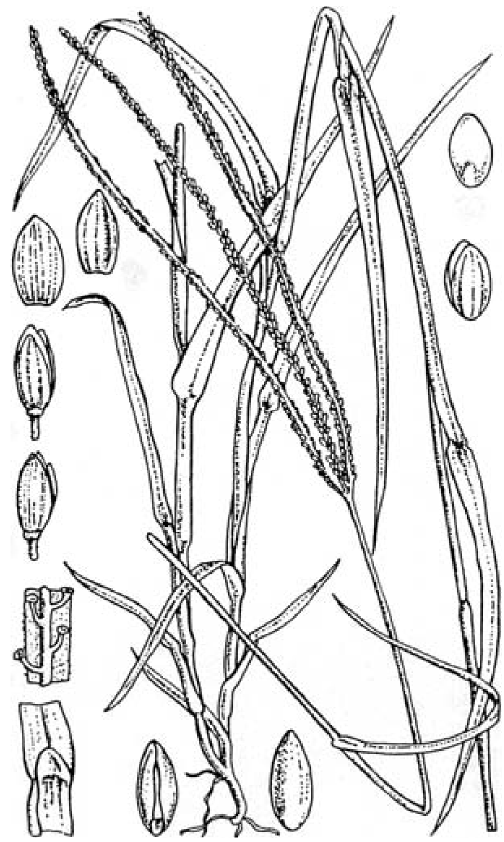

Figure 7 Vegetative and reproductive structures of fonio (*D. exilis*). The inflorescence is a digitate raceme with a winged rachis. (Reproduced with permission from Haq N (1995) A neglected cereal and two promising ones. In: Willams JT (ed.) *Cereals and Pseudocereals*. Chapman and Hall.)

tetraploid and the wild diploid species, *Aegilops tauschii* (D-genome). By comparison with the A^uB-genome tetraploids, diversity in the hexaploid group is relatively low.

The *T. boeoticum* line of domesticated wheat evolution has produced fewer and less important wheats, all hulled – *T. monococcum* (diploid; Figure 6), *Triticum timopheevii* (tetraploid), and *T. zhukovskyi* (hexaploid). *T. timopheevii* evolved from the wild species *T. araraticum*, which formed from a hybridization event between *T. boeoticum* and *Ae. speltoides*, here designated as donating the G-genome. *Triticum araraticum* is almost indistinguishable morphologically from *T. dicoccoides*, understandable given the similarities in their genome constitutions. *T. timopheevii*, and the related hexaploid *T. zhukovskyi* (A^mA^mG-genomes), have a limited distribution in the Transcaucasus region and display little infraspecific diversity.

Although the wheats are distinctive among the major cereals for the absence of intergrading crop–weed complexes, there is evidence of gene flow between wild and domesticated species. The wild tetraploid *Ae. cylindrica* (jointed goatgrass) is spread across Eurasia and has been introduced into North America where it has become a serious wheat-field weed. Recent studies suggest that hybridization between jointed goatgrass and bread wheat may involve gene flow of domesticated genes into the wild species on the basis of their shared D-genomes. It is not yet clear whether more aggressive, weedy forms of jointed goatgrass have actually arisen as a consequence. Gene flow between weedy forms of *T. dicoccoides* and durum wheat is also suspected.

Minor Cereals

The major cereals discussed above actually represent only a small sampling of the diverse collection of grass species that have been domesticated. Table 2 provides a partial listing of lesser-known cereals that are currently, or at one time were, important crops. Some of these cereals are grown on an extensive scale or across large regions (foxtail millet); others are locally restricted (fonio, Figure 7). Their importance is measured by their place as a dietary staple for the cultures

that cultivate them. Many of these species have been supplanted by the major cereals. For example, proso millet (*Panicum miliaceum*), once cultivated widely in Europe and the United States, has ceased to have importance as a cereal in these regions. As discussed above, African rice (*O. glaberrima*), an important species of décrue agriculture on the river deltas of Central Africa, is gradually being replaced by *O. sativa*. In the case of mango (*Bromus mango*), a regional cereal of Chile and Argentina, expansion of wheat and barley cultivation in these countries led to its disappearance in the nineteenth century. Mango is now under development as a promising new cereal. Some minor grains are being rediscovered, as is the case with the hulled hexaploid wheat, *T. spelta*, which is now a major player in the specialty USA cereal market.

Wild grasses and partially domesticated grasses still play an important role in the diet for some subsistence agricultural cultures. In famine times, West African peoples gather the wild fonio species *D. longiflora* and *D. fuscescens*. The weedy oat species, *A. abysinnica*, forms an integral component of the seed mixture for wheat and barley fields in Ethiopia. Subsistence farmers on the Anatolian plateau of Turkey allow weedy forms of *S. cereale*, which are more cold- and drought tolerant than the wheat crop that they infest. In bad years, this harvestable weed crop provides the "Wheat of Allah" for this traditional culture.

Research Trends

Evolution of the cereal species continues under plant breeding programs and the application of biotechnology to traditional breeding methods. Two new cereal species, Triticale (× *Triticosecale*) and intermediate wheatgrass (*Thinopyrum intermedium*), are products of modern breeding programs. Triticale, now grown on a commercial scale in Europe and North America, was synthesized from an intergeneric hybridization between wheat and rye. Intermediate wheatgrass, a species reported to have been cultivated as an ancient grain crop in Western Asia, is under development as a promising perennial cereal crop.

Traditional breeding methods are now being combined with the more sophisticated tools of biotechnology to broaden the base of usable germplasm sources for interspecific and intergeneric crosses through which new genes for pest resistance, salt tolerance, improved protein quality, and other agronomic traits can be introduced into cereal species. Genetically engineered cultivars, with alien genes, are being developed to enhance nutritive value (e.g., vitamin A in the *O. sativa* "Golden rice" cultivar) or to improve agronomic quality (e.g., insect resistance with *Bt*-maize; herbicide resistance in wheat). Whether by traditional methods or with biotechnology, the same fundamental mechanisms are at play, with humans acting as selection agents in furthering the evolution of cereals.

CHEMICALS FOR GRAIN PRODUCTION AND PROTECTION

P C Annis, CSIRO Entomology, Canberra, ACT, Australia

Introduction

Chemicals have a critical role in modern cereal production and are used at all points in the grain production and storage cycle, from seed dressing, through to soil preparation, to crop, and stored-product protection. There are several classes of agro-chemicals associated with grain production and protection. These include seed dressings, trace elements, fertilizers, herbicides, crop-protection pesticides, stored-product pesticides, structural treatments, and rodenticides. Trace elements, fertilizers, herbicides, and crop-protection pesticides are often very specific for particular biogeographical and agro-geographical situations and represent a diverse range of chemicals.

Chemicals used for structural treatments of storages, stored products, seed storage, and rodenticides tend to be more universal and cover a much smaller range.

In most jurisdictions, there are specific regulations concerning the use, supply, labeling, transportation, storage, and importation of pesticidal chemicals (insecticide, acaricide, rodenticide, fungicide, nematicides, molluscicide, and herbicide). The administration of these regulations may be associated with the authorities concerned with environment, public health, workers' safety, and agriculture. The specifics of the regulations may differ from place to place but the general rule is that a chemical may only be used in compliance with the label accompanying the product. This label will be specific to a particular jurisdiction. The label will contain specific information about what crops the material can be used on, what pests it is intended for, how to apply and rates of application, withholding times for treated crops, disposal of containers, personal/environmental safety, and first aid.

Registration is normally granted when it is shown that a pesticidal chemical can be used in compliance with all regulations, and there is a label that, when followed, will ensure that the user will meet regulatory requirements. The registration of agricultural chemicals is usually handled by a government agency. In the United States of America, this agency is the Environmental Protection Agency (EPA); in Australia, it is the Australian Pesticides and Veterinary Medicines Authority (APVMA); in the United Kingdom, it is The Pesticides Safety Directorate (PSD); other countries have equivalent bodies.

Trace elements and fertilizers are not generally subject to specific government registration. Application rates and methods of use will usually depend on local agronomic requirements and practice.

There have been many concerns expressed regarding the use of all chemicals in agriculture over recent years. However, their use continues because their role

remains an important part of food production, handling, and storage. Considerable effort has been directed since the 1980s to finding ways of using agro-chemicals (biocides and fertilizers) in a way that is sustainable, environmentally safe, and with minimal threat to the health of agricultural workers or consumers.

Although many agricultural chemicals are potentially dangerous, they should pose little threat if used strictly in accordance to the manufacturers' instructions. Risks are further reduced if the user reads and understands a "material safety data sheet" (MSDS) for the chemical concerned. In many jurisdictions, an MSDS must be available to people that handle, store, or use potentially dangerous goods.

The aim of this article is to provide an overview of the diverse range of chemicals used in grain production and storage, and to give a brief insight into their use and composition. Any detailed discussion of this subject would entail a review of large portions of the subject matter contained in the sciences of agronomy, economic entomology, plant pathology, and stored-product technology.

Seed Treatments

Fungicides

Fungicidal seed dressings are sometimes applied to stored seed to prevent disease development, which would impair the seed's ability to germinate, or the seedling's ability to grow in a normal manner. Fungicides are not generally used to prevent the development of storage fungi, which are better controlled by maintaining the seed in cool dry storage conditions. Germination is best maintained under conditions where fungal growth is not a problem. The optimum conditions for seed storage are well documented and have been known for many years.

Recommendations for the use of fungicidal seed dressings will vary with the prevalence of particular disease risks, national and state regulations, and availability of chemicals. Fungicidal seed dressings are particularly useful in cereal crops for controlling bunt and smut, and can assist in reducing the rate of development of some rusts. The following is a synopsis of the recommendations for bunt control in the State of Queensland, Australia. It is shown in order to give an idea of the role of preplant fungicides.

- Seed that is sown to provide the following season's seed needs to be treated with a fungicidal seed dressing.
- Seed from plants grown from untreated seed should be treated with a fungicidal seed dressing before planting.
- All seed entering Queensland should be treated with an appropriate fungicidal seed dressing.
- Grain from a crop with bunt should not be used for seed.
- Wheat seed from farms where a crop has been affected by bunt should be treated with fungicidal seed dressing for at least 6 years.

In Australia, fungicidal products containing the following active compounds are available, either singly or as components of a mixture, for seed dressings to control bunt (and some other seed-borne fungal diseases): carboxin, fluquinconazole, flutriafol, tebuconazole, thiram, triadimenol, and triticonazole.

Almost all chemical treatments have some disadvantages as well as the obvious advantages. The use of a fungicidal seed dressing, in general, renders the seed unfit for animal or human consumption, while a number of fungicidal seed dressings may reduce or retard seedling emergence. This is a problem that may be aggravated where the seed is sown in suboptimal conditions.

Fertilizers

There are many parts of world where additional phosphorus and/or nitrogen is essential to maintain a viable cereal cropping industry. The requirements for the other nontrace nutrient elements – potassium, calcium, magnesium, and sulfur – are less common and more localized.

Nitrogen

Cereal cropping removes nitrogen from the soil and, in almost all cases, that nitrogen will need to be replaced in order to allow sustainable cropping. Crop rotation with nitrogen-fixing plants and animal grazing has been used traditionally to replace soil nitrogen. Application of nitrogen fertilizer has now become standard practice for cereal grain producers in many parts of the world. The major nitrogen (N) fertilizers are: ammonium nitrate (34% N), urea (46% N), anhydrous ammonia (82% N), and urea–ammonia nitrate mixtures (ammonium nitrate and urea dissolved in water containing 28–32% N).

The cost and availability of nitrogen fertilizers varies greatly depending on location. Liquid urea–ammonium nitrate is often the most expensive treatment. The dry forms are intermediate and anhydrous ammonia is the most economical. Ammonia can, in some places, cost as much as 30–40% less for an equal amount of nitrogen, compared to the dry and liquid nitrogen forms. However, the complexity and costs associated with logistics and supply of ammonia make its use impractical in some regions.

Phosphorus

Phosphorus-containing fertilizers, like nitrogen-containing ones, are widely used in cereal growing. In places where the soil is low in phosphate, fertilizer addition is essential to give and maintain viable cereal yields. In recent years, concerns have been expressed about the effects of phosphate fertilizers on the surrounding environment associated with soluble phosphate ending up in waterways. This has led to several jurisdictions formulating guidelines for the application of phosphate fertilizers (also other fertilizers).

Phosphorus is applied as ammonium phosphates or superphosphate, and phosphorus fertilizers are often characterized by their (N–P–K) composition. Common phosphate fertilizers include liquid ammonium polyphosphate (10–34–0), dry mono- or di-ammonium phosphate (11–48–0, 16–48–0, or 18–46–0), superphosphate (0–20–0), or concentrated superphosphate (0–45–0).

Sulfur

Sulfur-deficient growing conditions are much less common than is the case for nitrogen or phosphorus. The most common sulfur-supplying fertilizers are ammonium sulfate or gypsum. These are best applied as top dressing where they are immediately taken up by wheat plants. Elemental sulfur may have some role as a preplant sulfur source. However, it is chemically unavailable to the plant when used as top dressing for growing plants.

Potassium

Potassium deficiency can limit wheat crop growth but the deficiency is not common. There are some restricted localities around the world where the use of a potassium-supplying fertilizer is useful. Potassium is usually applied as either potassium chloride (~60% K) or potassium sulfate (50% K). Potassium nitrate (37% K), another potential fertilizer, is not commonly used for cereal crops.

Calcium and Magnesium

There may be a need for additional calcium and magnesium in leached soils in high rainfall and acid-rainfall areas. Calcium is frequently obtained coincident with liming as part of soil pH control. Both calcium and magnesium can also be supplied by adding crushed limestone.

Trace Elements

Deficiency of trace minerals such as boron, iron, zinc, manganese, molybdenum, and copper can be limiting to crop growth and health. Seed dressings along with foliar sprays are often effective in correcting nutrient deficiencies, particularly when used in combination with other ameliorating techniques (e.g., soil sprays, nutrient-enriched granular fertilizers). Seed dressing with trace minerals is rarely adequate on its own. Where no nutrient deficiency exists, the application of trace element seed dressings and foliar sprays may be of little benefit. Trace element deficiencies can be localized to very small areas, and are rarely general over wide regions or countries. Trace element deficiency is usually first recognized as a possibility by defects in plant growth. However, the visual symptoms of a particular deficiency can be confused with those produced by a range of other crop growth problems. Diagnosis of a trace element deficiency should be verified by plant and/or soil analysis where this is possible.

Herbicides

Herbicides are used both as a component of zero- or low-till agriculture and for weed control in the growing crop. Herbicides are best used when the weeds are young and actively growing. Both weed and crop growth stages are critical to the successful use of postemergence herbicides. Cereal species and varieties can vary widely in their herbicide tolerance. As is the case with the use of all bioactive chemicals, it is important to read labels carefully for details on crop tolerance and information on optimum and safe application conditions.

Many broad-leaf weeds can be economically controlled using a strategic application of a postemergence herbicide. Some grassy weeds such as wild oats, annual ryegrass, and phalaris can also be controlled. This can be achieved by carefully controlled pre- or postsowing spraying in some cereals but not all. There are other grassy weeds in cereals that cannot be controlled with herbicides.

Some weed species, particularly grasses, germinate throughout the growing season, especially in grazed crops, when ground cover is reduced and soil temperatures rise. In this case, two herbicide applications at different growth stages could be warranted. For example, an early postemergence spray may not completely control weeds such as wild radish and a late application can be justified to minimize seed set and seed harvested with the grain.

In Australia, the following active compounds are registered as herbicidal preparations for various phases in the cereal growing cycle; they may either be registered as components of a mixture or singly or both.

- *Presowing and seedbed preparation.* Chlorsulfuron, oyzalin, pendimethalin, sulfosulfuron, triallate, trifluralin, and triasulfuron.
- *Salvage seedbed preparation.* 2,4-D, dicamba, diquat, glyphosate, glyphosate trimesium, and paraquat.
- *Early postemergent.* 2,4-DB, bromoxynil, chlorsulfuron, clodinafop-propargyl, clopyralid, dicamba, diclofop-methyl, diflufenican, diuron, fenoxaprop-p-ethyl, flamprop-M-methyl, flumetsulam, MCPA, metasulfuron, metosulam, picloram, sulfosulfuron, terbutryn, thifensulfuron, and tralkoxydim.
- *Late postemergent.* 2,4-D amine, 2,4-DB, 2,4-D ester, dicamba, flamprop-M-methyl, MCPA, flumetsulam, picloram, and triasulfuron.
- *Fallow and stubble weed management.* 2,4-D, 2,4-D amine, 2,4-D ester, diquat, dicamba, glyphosate, glyphosate trimesium, imazameth paraquat, tribenuron methyl, and triclopyr.

The label instructions for use of these materials are complex and specific and take into account a wide range of parameters, which include the occurrence of resistance, stages in the planting/growing cycle of the cereal, cereal variety, target weed species, and its stage in the growing cycle, crop stress, and local regulations.

Crop-Protection Chemicals

Insect pests of growing cereal crops will vary widely on a geographical basis. The situation in Australia gives an indication of the role for crop-protection chemicals, but each region will have its own suite of pests and its own range of allowable pesticides.

In Australia, lepidopteran larvae, a few mite species, and aphids pose the most common and widespread invertebrate threat to growing cereal crops. There are also occasional regional and severe outbreaks of Australian plague locusts, and there are some areas where white Mediterranean snails can cause problems in harvesting and marketing grain. There are times when mouse plagues are so severe that action is needed to prevent economic consequences. Some soil insects such as wireworms, false wireworms, wingless cockroaches, black field earwigs, and seed harvesting ants may cause economic levels of damage. Additional groups of pests in other parts of the world include Hemiptera, dipteran larvae, and thrips.

The precise chemical to use for a particular control need is too complex to consider here. In Australia, the United Kingdom, Canada, the United States, and many other countries, there are a series of electronic resources that make the selection of appropriate chemicals relatively simple. These assist in the decision process and help match the permitted use of the chemical to the target pest, the target crop, stage of crop growth, and withholding periods. The list that follows shows the suite of active compounds available in Australia for use on growing cereal crops for various broad taxonomic groups of pests. The complexities of registration mean that a chemical may not be appropriate for every species in the indicated group or indeed for every cereal crop.

- *For Lepidoptera.* α-Cypermethrin, Bacillus thuringensis preparations, β-cyfluthrin, carbaryl, chlorpyrifos, cypermethrin, deltamethrin, diazinon, esfenvalerate, malathion, methidathion, permethrin, trichlorfon, and ζ-cypermethrin.
- *For aphids.* α-Cypermethrin, β-cyfluthrin, dimethoate, and esfenvalerate.
- *For locusts and grasshoppers.* Carbaryl, chlorpyrifos, dimethoate, fenitrothion, and maldison.
- *For mites.* α-Cypermethrin, β-cyfluthrin, bifenthrin, chlorpyrifos, cypermethrin, dimethoate, λ-cyhalothrin, maldison, methidathion, omethoate, and phosmet.
- *For snails.* Methiocarb.
- *For mice.* Zinc phosphide.

Foliar Fungicides

The use of foliar fungicides is highly dependent on the suite of fungal pathogens present and the degree to which they present a risk to economic crop production. The nature of this risk will vary considerably between crops, from region to region, and in many cases from year to year. Region-based advice is usually required to determine the specific requirements for foliar fungicide application. This advice is available, depending on the country concerned, through a range of commercial, government, or university agencies. In recent times, many of these agencies have set up websites addressing this type of regional advice. A sample of these websites is included in the references at the end of this article.

While there is a wide range of fungicidal preparations, the number of active chemicals involved is relatively small. For example, in Australia the following are registered for application to growing cereal crops: benomyl, flutriafol, propiconazole, tebuconazole, terbufos, triadimefon, and tridemorph.

Stored-Product Protection

Chemical treatment of stored grains can have a profound effect in maintaining cereal stocks by reducing (almost eliminating) losses caused by animal

pests. In many climatic zones, long-term storage of grain without loss of biomass or quality would be almost impossible without some form of postharvest chemical treatment. Despite this, there is considerable pressure to reduce chemical treatments of grain in storage. This is largely based on the complexities of dealing with the residues that may be associated with the treatment.

In stored products, compared to field crops, these residues are much closer to the final consumer in the consumption chain. Unlike horticultural products that also have a short path to the consumer, grains have many end uses including: direct consumption without preprocessing by animals (and to a small extent humans), milling into multiple physical fractions, a raw product for extraction of chemical fractions (starch and gluten), a source of carbohydrate for the fermentation industry, and the base product for a whole range of manufactured human and animal foods. This means that treated cereals have multiple entry points for residues into food for human consumption, either directly or via animal products such as meat and milk. This complicates the pathway to registration to such an extent that it may become too hard to achieve within financial constraints.

Chemical Control

For the purpose of convenience, chemical use in grain storage may be divided into several broad groups: fumigants, where the active agents are gases or vapors; grain protectants, where the active agents are applied directly to the grain as liquids or powders; structural treatments, where they are applied within the structure but not directly to the grain; and low risk use chemicals, where the toxic agent has a low mammalian toxicity and limited environmental risk.

Fumigation As of 2003, phosphine and methyl bromide are the only two fumigants in widespread use for fumigation of grain and grain-storage structures.

Phosphine Phosphine is applied in two physical forms: as a metallic phosphide (usually aluminum phosphide) that reacts with ambient moisture to release phosphine, or as gaseous phosphine from pressurized cylinders. Phosphine is a relatively slow-acting fumigant and depending on concentration and target species takes from 5 to 25 days for complete disinfestation.

Phosphine is the more commonly used of the two major fumigants and is used under a wide range of conditions, many of which are well below those associated with good fumigation practice. A consequence of this widespread use is that the continued use of phosphine is threatened by the worldwide occurrence of resistant insect populations and concerns about risks to human safety associated with its application.

Methyl bromide Methyl bromide is a rapidly acting fumigant typically giving complete disinfestation in 12–48 h. This role is not sustainable, as it has been shown to be a potent stratospheric ozone-depleting substance. This means that its use has been severely curtailed, and under international treaty after 2005 it will only be available for genuine quarantine and related preshipment uses.

Fumigants under development Because of the importance of fumigation there has been considerable research into replacements for methyl bromide and alternatives to phosphine. Carbonyl sulfide, ethyl formate, and sulfuryl fluoride all show some promise at the research level. They are not yet available for commercial use on grain and are unlikely to be commercially available for a further 2–3 years, even if the process of commercialization proceeds without problems.

Grain protectants Grain-protectant chemicals are designed to protect (as opposed to disinfest) grain. Early grain protectants included DDT and dieldrin in the 1940s and 1950s. Newer, less persistent chemicals replaced them in the 1960s. By the mid-1980s a suite of ~21 grain-protectant chemicals were either available or close to being commercialized. The number has fallen considerably since then and, by 2003, in Australia only carbaryl, chlorpyrifos, cypermethrin, deltamethrin, dichlorvos, fenitrothion, malathion, methoprene, and pirimiphos-methyl remain. Of these, some are not available for grains destined for some specific end uses. For example: carbaryl can only be used on feed grain; cypermethrin can only be used on seed grain; only low doses of methoprene and no chlorpyrifos methyl can be used on malting barley; and no deltamethrin can be used on export grain for some destinations. Other chemicals, such as malathion, have considerable resistance problems and finally a few like dichlorvos are under active regulatory review.

A further complication is that many of these materials are required to be part of a mixture to ensure a complete kill of all insect pest species. In some parts of the world, the list of registered materials is even smaller; for instance, in the UK only chlorpyrifos and pirimiphos-methyl are listed for use on stored grain.

It appears that grain-protectant chemicals only have a limited future in many parts of the world and alternatives such as fumigation, controlled atmosphere, and physical methods will have to become much more common.

Controlled atmospheres Controlled atmospheres can be thought of as a special case of fumigation or as low-risk chemical treatments. The gases used are normal components of the atmosphere and biological systems. The gases most commonly used are nitrogen to displace oxygen, and carbon dioxide as a toxic agent in its own right. Costs and logistics limit the use of these treatments. Long exposure times (typically 15 days or longer), high level of sealing, and the large volumes of gas required to establish or maintain concentration of $>40\%$ for carbon dioxide and 99% for nitrogen ($<1\%$ oxygen) are the main constraints. However, both types of controlled atmospheres are used where these factors are not limiting, or where special requirements exist.

Structural treatments There is a range of chemicals that can be used to treat empty grain storages, grain handling, and harvesting equipment. This is a slightly larger range of chemicals than that available for direct application to grain. It is generally recognized that insect pests associated with residual grain and other plant residues/dust are best dealt with by removing the residues rather than chemical treatment. Nevertheless, there are occasions where a somewhat persistent surface treatment or time-release chemical space treatment may be useful as an adjunct to but not a replacement for good hygiene.

Registration of chemicals for structural treatments vary greatly, but in Australia the following are registered for use in structures where there is no chance of direct application to grain (however, some do have separate registration for direct application to grain): amorphous silica, azamethiphos, deltamethrin, dichlorvos, phosphine, methyl bromide, and pyrethrins plus piperonyl butoxide.

Rodenticides

Chemical control of rodents is an integral part of stored-grain management. In grain storages, unlike most industrial and domestic situations, it is almost impossible to control populations by isolating the rodents from their food. In grain storages, there is an ever-present, easily available food resource. Physical isolation of that resource from the outside environment is often impractical. There are also obvious risks associated with using a chemical designed to kill mammals in close proximity to a major human and domestic animal food.

The range of behavioral and physiological adaptations available for the target organisms means that rodent control strategies have to be well-planned to be successful. There is a fairly wide range of active materials that allow a flexible range of control to fit with the circumstances surrounding the need for rodent control. Factors influencing choice include the severity of infestation, the proximity of the stored grain, the previous history of treatment, the phase in the rodent control cycle (disinfestation or maintenance), the species present, physiological resistance, bait shyness, and the risks to nontarget species including humans.

The following active compounds are available in Australia for use in and around grain stores: brodifacoum, bromadiolone, cholecalciferol (vitamin D_3), coumatetralyl, flocoumafen, strychnine, warfarin, and zinc phosphide. In the UK, the list is similar but does not include strychnine. A similar range of materials is permitted in most other countries.

CHICKPEA

Contents

Overview

E J Knights, Tamworth Agricultural Institute, Tamworth, NSW, Australia

Introduction

Chickpea was one of the first legume crops domesticated. Today it is a key component of cropping systems in many parts of Asia and Africa, providing families of resource-poor farmers with a valuable source of dietary protein. Chickpea is also becoming established in some agriculturally advanced nations in response to a growing world demand. This article describes the species, its uses, and role in farming systems around the world.

Biology

Chickpea (*Cicer arietinum* L.) is a herbaceous, annual legume. Plants are typically short (20–50 cm) with a semi-erect to erect growth habit and a variable number of primary and secondary branches. An imparipinnate leaf type, producing 11–18 small leaflets, gives the foliage its distinct fern-like appearance (Figure 1). Chickpea is a long day plant; however, time to flowering is accelerated by increasing temperature. Flowering is indeterminate with single (rarely double), small purple or white flowers produced on racemes arising from the leaf axil. Pods have a characteristic oval to rhomboid shape and inflate rapidly after (self-) fertilization (Figure 1). All aerial plant parts excepting flowers have a dense covering of fine hairs which secrete a mixture of organic acids. Roots are colonized by *Mesorhizobium ciceri*, a nitrogen-fixing bacterium specific to the genus *Cicer*. Nodules formed by these bacteria vary in size, the largest approaching 3 cm in diameter.

The seed is highly variable in appearance but invariably possesses the characteristic chickpea "beak" protruding over the embryo. Seed shape, color, and, to a lesser extent, size separate the species into three main groups: "desi," "kabuli," and "pea" (Figure 2).

Figure 1 Chickpea branch showing typical leaf and pod shape. (Chickpea normally produces single, axillary flowers; the "double-podded" variant shown here may confer some yield advantage in low productivity environments.)

Figure 2 Seed type in chickpea showing, clockwise from top of picture: kabuli, desi, and pea (intermediate) forms.

Desi (derived from the Hindi and Urdu word for "native" or "local") seeds have an angular shape and thick, colored (mostly brown) seedcoat. In contrast, kabuli seeds have a more rounded shape and thin, white to cream seedcoat. There is considerable overlap between these two seed types in seed size; however, desi seeds are generally smaller (weighing 80–350 mg) than kabuli seeds (100–750 mg). The pea-type seed has little commercial significance.

Origin and Spread

The genus *Cicer* contains 43 species, 34 perennial, and 9 annual. All annual species are diploids and have 16 chromosomes ($2N = 16$). Amongst these, *C. reticulatum* is the most closely related to the cultivated chickpea and the presumed progenitor. Domestication occurred about 10 000 years ago in the region centered on south-eastern Turkey, part of the "Fertile Crescent." This would have involved a number of steps, including selection for more erect plant type, reduced pod shattering, and palatable, nondormant seeds. About 4000–5000 years ago the domesticated forms, initially desi types, commenced a westward movement along established trade routes toward the Mediterranean. Subsequent spread to southern Europe and North Africa, including Ethiopia, occurred by land and/or sea routes. Differentiation of the kabuli type is thought to have occurred in the Mediterranean region in comparatively recent times. The eastward movement of desi types to India commenced about 4000 years ago, whereas kabuli types did not arrive there until about 300 years ago. (The prominence of Kabul on the "Silk Road" suggests both an overland introduction and the origin of the word "kabuli.") In the sixteenth century Spanish and Portuguese travelers carried kabuli types to South and Central America where they came to be known by their Spanish name "garbanzo." Chickpea industries have comparatively recent histories in the USA (1950s), Australia (1970s), and Canada (1990s).

Production

During the 1990s world chickpea production has averaged 8 million tons (Mt) from 10.5 million hectares (Mha). Crop area now is similar to that in the early 1960s; increased production since then has been generated by higher yields (Figure 3). Historically, Asia has been the major chickpea producer. For the five years 1997–2001, it accounted for 87.4% of all production, followed by the Americas (5.5%), Africa (3.9%), Australia (2.5%), and Europe (0.8%). Desi types contribute ~80% of production worldwide.

Chickpea is cropped in ~50 countries. India still produces two-thirds of the world crop (Table 1) despite a steady decline in the area sown. A similar trend has occurred in Pakistan, the world's second largest producer and, more dramatically, in European countries where chickpea area has fallen by 60–97% since the 1960s. On the other hand, production has risen significantly in some countries. In Turkey, the world's third largest producer, chickpea area increased rapidly during the 1980s as fields previously left fallow after cereals were sown to chickpeas. New chickpea industries in Australia and Canada have also helped stabilize or even increase world production in recent years.

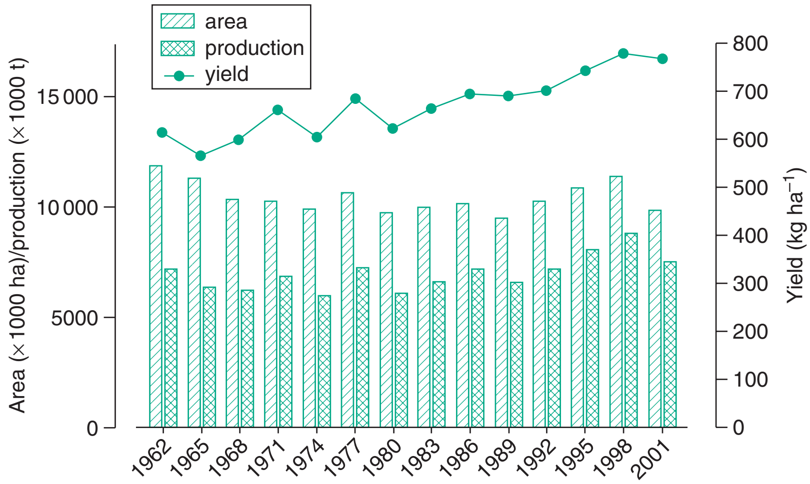

Figure 3 World area, production, and yield of chickpea, 1961–2001. Each datum is the mean for a three-year period. (Source: FAO.)

Table 1 Mean area, production, and yield of chickpea in major chickpea-producing countries (1997–2001)

Country	*Area (ha)*	*Production (t)*[a]	*Yield (kgha^{-1})*
India	6 783 000	5 427 840 (66.4)	796
Pakistan	1 031 240	604 180 (7.4)	581
Turkey	658 400	597 600 (7.3)	905
Iran	649 480	238 236 (2.9)	366
Canada	162 080	219 880 (2.7)	1351
Mexico	136 167	219 947 (2.7)	1593
Australia	245 400	204 168 (2.5)	869
Ethiopia	180 901	164 917 (2.0)	917
Myanmar	127 607	89 880 (1.1)	705
Syria	88 349	59 400 (0.7)	660
Spain	88 320	52 600 (0.6)	591

[a] Percentage of world production in brackets.
Data from FAO.

Average world yield over the period 1997–2001 was 773 kg ha^{-1}. Central and North America had the highest yields (1483 kg ha^{-1}) followed by Australia (869 kg ha^{-1}), Asia (750 kg ha^{-1}), Africa (689 kg ha^{-1}), and Europe (625 kg ha^{-1}). Yields were generally highest in countries where all or most of the crop was irrigated, such as Lebanon (2367 kg ha^{-1}), Israel (1886 kg ha^{-1}), and Egypt (1792 kg ha^{-1}).

Consumption and Trade

Chickpea is an important part of the diet in most producing countries and is gaining in popularity elsewhere. Per capita consumption is generally much higher in producing countries, such as India (5.1 kg pc) and Pakistan (4.4 kg pc), than in developed, nonproducing countries such as the United Kingdom (0.2 kg pc). Consumption is also comparatively high in some wealthier, producing countries such as Turkey (6.3 kg pc) and Spain (2.3 kg pc).

Historically, most chickpeas were consumed in their country of origin. Until the late 1970s, international trade accounted for only 2% of world production. This percentage rose to 8% in the following two decades as demand exceeded supply in major producing countries, especially in east Asia. During the period 1996–2000, India was the largest importer (138 000 t) followed by Pakistan (60 000 t) and Spain (56 000 t). For the same period, Australia was the largest exporter (240 000 t), followed by Turkey (153 000 t) and Mexico (132 000 t). The volumes of desi and kabuli types now traded are similar. Prices fluctuate according to supply and demand; however, there is generally a premium for kabuli types and particularly for those with large seed (diameter > 10 mm).

Role in Farming Systems

Chickpea is grown in a range of environments encompassing extensive variation in latitude (53° N to 39°S), altitude, soil type, photoperiod, temperature, and rainfall. Seven broadly different regions can be distinguished.

Indian Subcontinent (India, Pakistan, Nepal, Bangladesh, and Myanmar)

Desi types predominate in this region, accounting for more than 90% of production. Chickpea is typically grown as a "winter" crop with sowing from October to December and harvest from February to April. The crop is mostly rainfed, relying essentially on soil moisture conserved from monsoon rains; there is little effective growing season rainfall. Soil types vary from the heavy, black "cotton" soils of central and southern India to the alluvial soils of the Indo-Gangetic Plain and the much lighter textured sands of Rajasthan in India and the Thal area of Pakistan.

Chickpea is grown mainly as a sole crop in a range of rotations. Where sufficient rainfall or irrigation allows, e.g., in north western India or in the rice-based systems of north eastern India, Bangladesh, and Myanmar, chickpea follows rainy season crops such as rice, millet, sorghum, maize, sugar cane, cotton, guar, or sesame. However, in lower rainfall zones where only one crop per year is possible, chickpea is grown as a fallow crop. Less frequently, it is intercropped in varying proportions with *Brassica* spp., linseed, safflower, or sorghum, or sown as a mixed crop with wheat, barley, linseed, or sorghum.

Fertilizer and pesticide use is generally low and there is minimal mechanization of sowing, harvest, or weed, insect, and disease control. These operations are performed by hand or with the assistance of animal drawn implements. Mature plants are cut at the base by hand and left to dry in the field. They are later transported to a central area and threshed.

West Asia, North Africa, and Southern Europe

Production in this region is almost exclusively of kabuli types. The crop is grown at high altitudes in west Asia (Afghanistan, Iran, and Turkey) but at comparatively lower altitudes in the Middle East (Syria, Yemen, Jordan, Israel, and Iraq), North Africa (Egypt, Sudan, Algeria, Tunisia, and Morocco), and southern Europe (Greece, Italy, Spain, and Portugal). It is grown as a "spring" crop in this Mediterranean-type environment, relying mainly on growing season rainfall. Sowing is usually delayed until late February to May to minimize losses from cold and/or ascochyta

blight. Rapidly increasing temperatures and moisture stress in summer hasten maturity and limit crop duration to 90–120 days.

Chickpea is generally confined to areas having an annual rainfall above 400 mm. It is grown as a sole crop in rotation with wheat (bread or durum) or barley; a fallow phase or summer or forage crop may be included in drier areas. There is some mechanization of production, particularly sowing and weeding, but harvest is still largely manual. High labor costs have contributed to the decline in chickpea production in parts of the region, especially in Europe.

East Africa (Ethiopia, Eritrea, Tanzania, Malawi, and Uganda)

Mostly desi and some kabuli chickpeas are grown in this region, usually at high altitudes (up to 2400 m). Crops are mainly sown as pure stands in rotation with wheat, barley, and tef, but to a lesser extent as mixtures with sorghum, safflower, and maize. Crop growth relies mainly on residual soil moisture. Sowing follows the wet season, from July to early September in Ethiopia and from February to April further south. Inputs of fertilizers and pesticides are minimal, and although there is some use of tractors in sowing, harvest and threshing remain manual operations.

Central America (Mexico)

Desi chickpeas are produced under rainfed conditions in the west-central parts of the country and kabuli types under irrigation in the drier northwest. Chickpea is grown as a "winter" crop following maize in the westcentral region and following soybean or sesame in the northwest. Sowing is from October to December and harvest from March to May. There has been some recent transition to mechanized production, particularly for kabuli types.

North America (Canada and USA)

The North American chickpea industry began in coastal districts of California where spring-sown kabuli crops were grown on residual soil moisture. Later, winter crops were grown under irrigation in the drier San Jaoquin Valley. During the 1980s, both desi and kabuli chickpeas were introduced to the Palouse region of northwestern USA and, in the following decade, to the brown and dark brown soil zones of Saskatchewan and Alberta in Canada. The threat of cold and ascochyta blight force chickpeas to be grown as a "spring crop" in both the Palouse and Canada. Sowing commences in May and harvest, particularly in Canada, needs to be completed by September to avoid freezing injury to immature seeds.

In the USA and Canada all stages of chickpea production, including seed inoculation, sowing, weed, disease and insect control, harvest, and seed drying are highly mechanized. In most cases the machinery and processes have been modified from those used in cereal production.

Australia

Production is mainly (>90%) of desi types and occurs in two distinctly different environments in Australia: the summer rainfall-dominant regions in the northeast and the winter rainfall-dominant Mediterranean-type environments in the southeast and southwest. Chickpea is grown as a "winter" crop, sown from May to July and harvested from October to January. Most crops are produced under rainfed conditions; in-crop rainfall is a major yield determinant in most regions, especially in the southeast and southwest. As in North America, production is highly mechanized. Control of ascochyta blight, the major industry problem in most regions, relies heavily on ground rig application of foliar fungicides. Application of insecticides by plane to control pod borers is also widely practiced.

Production Constraints

There is a large discrepancy between the yield in farmers' fields and that commonly obtained under experimental conditions. The low yields generally obtained by farmers reflect a plethora of problems that beset the crop. The major production constraints and their impacts are described below.

Physical Constraints

Drought Chickpea is mostly grown in low rainfall environments. Inadequate soil moisture is therefore a critical production constraint and may occur throughout the growth cycle. Winter/spring rains in west Asia, or soil moisture remaining from the wet season in the Indian subcontinent and east Africa, may not be sufficient for farmers to sow; for many regions variability in main season rainfall explains much of the year-to-year variation in chickpea area. Receding soil moisture, particularly in low rainfall areas in India and Pakistan, may also be inadequate to sustain seedlings. Intermittent moisture stress of established crops can result from breaks in winter and early spring rainfall, but a more serious problem is terminal moisture stress suffered by spring-sown crops (and winter crops in the Indian subcontinent) as podding coincides with rapidly declining soil moisture.

Cold Low temperatures affect the plant in two main ways: tissue damage through disruption of cell membranes and abortion of flowers. Sensitivity to low temperatures ($<-5°C$) is one reason for spring sowing in higher elevation areas of west Asia. However, genotypes have now been identified which can survive temperatures as low as $-25°C$. Winter sowing of these cold tolerant genotypes can increase yield potential by $\sim$70% through increased biomass production and improved water-use efficiency. Where the crop is sown in autumn/winter, such as in northern India, Pakistan, and Australia, chilling damage in the early flowering phase narrows the "window" for pod setting. Sowing is normally delayed so that commencement of flowering coincides with mean daily temperatures favorable for podding (15°C).

Hostile soils A range of soil chemical and physical problems limit chickpea growth. The most important of these is salinity, since chickpea is comparatively intolerant of the ionic imbalances characteristic of "saline" soils. "Sodic" soils, in which high levels of exchangeable sodium are associated with increased bulk density, low water infiltration, and poor aeration, are also common in northern India and in other regions where soil pH is very high. Retarded root growth and poor nodulation inhibit chickpea growth and productivity under such conditions. Other locally important soil factors are acidity (poor nodulation), deficiencies of iron and zinc, and either a deficiency or toxicity of boron.

Diseases

Ascochyta blight Ascochyta is the most important disease of chickpea worldwide and has been recorded in nearly all producing countries. Recent epidemics in the USA (1980s) and Australia (1990s) caused major industry disruptions, reflected by a sharp decline in the area sown. Elsewhere, for example, in west Asia and the Mediterranean region, the threat of ascochyta causes sowing to be delayed, thereby significantly reducing yield potential. The causal agent of ascochyta is *Ascochyta rabiei* (Passerini) Labrousse, a fungus spread by infected seed and crop residues, long-range dispersal of sexually produced ascospores, or, within the crop, short-range dispersal of asexually produced pycnidiospores. Lesions are formed on leaves, stems, pods (Figure 4), and seeds. The disease progresses quickly under favorable wet conditions and can cause total crop failure. Ascochyta can be controlled by an integrated disease management approach based on host resistance and, depending on location, including removal of infected plant debris, delayed sowing, seed dressing, and foliar fungicides.

Figure 4 Ascochyta blight on pods. The concentric rings of dark colored pycnidia (fruiting bodies) are a useful diagnostic feature for this disease in chickpea.

Other foliar diseases Botrytis gray mold (*Botrytis cinerea* Persoon: Fries) is the most important of the foliar diseases after ascochyta. The pathogen has a very broad host range; therefore, the disease is widely distributed. Most damage occurs under high humidity and generally at temperatures higher than optimum for ascochyta. Botrytis has contributed to the decline of the Bangladesh chickpea industry and has also caused significant or total crop losses in the higher rainfall zones of northeastern India and in Australia. The following diseases are also regarded as locally significant: sclerotinia stem rot (*Sclerotinia sclerotiorum* (Lib.) de Bary), phoma blight (*Phoma medicaginis* Malbr. and Roumeguère), alternaria blight (*Alternaria alternata* (Fries:Fries) Keissler), stemphylium blight (*Stemphylium sarciniforme* (Cavara) Wiltshire), and rust (*Uromyces ciceris-arietini* Jaczewski in Boyer & Jaczewski).

Fusarium wilt Fusarium is the other major disease of chickpea, and like ascochyta, causes economic damage in a large number of producing countries. It is a soil and seed-borne disease caused by the fungus *Fusarium oxysporum* Schlecht:Fries emend. Snyder and Hansenf. sp. *ciceris* (Padwick) Matuo & Sato. Characteristic wilt symptoms appear from the seedling stage, in highly susceptible varieties, through to the podding stage. Fusarium is more frequently expressed under warm, dry growing conditions and is therefore a greater problem in the Indian subcontinent and in regions where the crop is spring sown. Fungicidal seed dressings provide protection against seed-borne infection, but host resistance is emerging as the most successful way of combating the disease.

Root and collar rots A number of fungal root or collar diseases have the potential to inflict significant yield losses. Black root rot (*Rhizoctonia bataticola* (Taubenhaus) Butler) is the most important of these, especially on the Indian subcontinent. The disease generally presents as a sudden drying of scattered plants at the podding stage and is favored by hot, dry conditions. Other diseases include wet root rot (*Rhizoctonia solani* Kühn), black root rot (*Fusarium solani* (Maartius) Saccardo), collar rot (*Sclerotium rolfsii* Saccardo), and phytophthora root rot (*Phytophthora medicaginis* Hansen and Maxwell). The latter has been recorded in a number of countries, but economically significant damage has only been observed in northeastern Australia where it is the major production problem.

Viruses Considerable crop losses have been attributed to virus disease, especially in India, Pakistan, Iran, the USA, and Australia. In most cases a complex of viruses has been implicated. Aphids, particularly *Aphis craccifora* Koch, are almost always the vector responsible for disease transmission. In India chickpea stunt is the name given to a syndrome characterized by foliage discoloration (red in desi, yellow in kabuli), stunting, phloem browning, and plant death. The disease has been ascribed to the leafhopper-transmitted chickpea chlorotic dwarf virus (CCDV) and some aphid-transmitted luteoviruses, including bean leafroll luteovirus (BLRV). Other viruses known to cause disease are alfalfa mosaic virus (AMV), cucumber mosaic virus (CMV), beet western yellows virus, and subterranean clover redleaf virus (SCRV).

Nematodes Nematodes reduce yield by colonizing and damaging roots, reducing the efficiency of nitrogen fixation and in some cases acting synergistically with fungal diseases such as fusarium wilt. Many nematode species are known to infect chickpea although only three are considered economically important. Root-knot nematodes (*Meloidogyne* spp.) cause abundant formation of galls, whereas both cyst nematode (*Heterodera ciceri* Vovlas, Greco & di Vito) and root-lesion nematodes (mainly *Pratylenchus thornei* Sher and Allenand and *P. neglectus* (Rensch) Chitwood and Oteifa) damage root cellular tissue causing necrotic regions. Root-knot nematodes and root-lesion nematodes have an extensive host range and are widely distributed; cyst nematode has a very limited host range and its distribution is confined to the Middle East.

Insects

The small number of insect pests causing economic damage to chickpea is attributed to the antibiotic effect of the plant's acidic (mainly malic acid) exudate. The most widespread and damaging pest is the pod borer (*Helicoverpa* spp.). Various larval instars feed on leaves, flowers, and pods. Most yield loss is caused when late instar larvae enter the pod and partly or fully consume the developing seed. There is little effective host resistance within chickpea so control is reliant on a combination of chemical and bio-pesticides (such as nuclear polyhedrosis virus). The other major field pest is leaf miner (*Lyriomyza cicerina* (Rondani)) whose distribution is confined to the Mediterranean region. Larvae tunnel through the leaf parenchyma causing loss of photosynthetic tissue and premature leaf drop. Infestation of stored seed is mainly by small bruchid beetles (*Callosobruchus* spp.). Larvae emerge from eggs laid on the (stored) seed surface and tunnel beneath the seedcoat where they feed and pupate. Adults emerge from the seed, ready for the next life cycle and leaving a substantial cavity.

Weeds

Chickpea's slow early growth and low total biomass predispose the crop to severe weed competition. In most countries weed control is done by manual weeding or cultivation by animal- or tractor-drawn implements. These practices are feasible where crop area is small, although yield potential is often compromised where wide rows are employed to facilitate cultivation. Options for pre- and post-emergent control of both grass and broadleaf weeds are now available and used extensively in Australia, the USA, and Canada. Grass herbicides are very effective, have no toxicity to chickpea, and contribute to the productivity of ensuing cereal crops by eliminating graminaceous diseases that can otherwise survive on grass weeds.

Utilization

Nutritional Status

Desi chickpea seeds are comprised of the embryo (1.5%), seedcoat (15.5%), and cotyledons (83%); the seedcoat fraction of kabuli seeds is much lower (6.5%), resulting in a higher cotyledon fraction (92%). Protein averages 23% and is deficient in the sulfur-containing amino acids methionine and cystine. Carbohydrate, the main constituent, averages 63.5% of total seed and is mainly starch. Soluble sugars comprise $\sim$10% of the starch and include oligosaccharides such as stachyose and raffinose that cannot be broken down by human digestive enzymes. Gases produced by bacterial degradation of these oligosaccharides cause flatulence and intestinal discomfit. Oils comprise $\sim$5% of the seed but are well below commercially extractable levels. Chickpea is

Table 2 Main uses of chickpea for human consumption

Plant/seed part used	*Process/product*	*Country/region*
Green leaves	Boiled as vegetable	Indian subcontinent (ISC)
Immature plant	Roasted, pods shelled	ISC, Middle East, Ethiopia
Unripened pods	Pods shelled, seeds raw or boiled	ISC, Ethiopia, Turkey
Whole seed – kabuli	Soaked, boiled alone or with vegetables, rice, meat, spices	Most countries
	Soaked, boiled, canned	North America, Europe, Australia, Middle East
	Soaked (briefly), roasted	Middle East, North Africa
	Soaked, boiled, pureed (Hommos)	Middle East, North Africa
Whole seed – desi	Soaked, boiled with vegetables, rice, spices	ISC
	Soaked (briefly), roasted	ISC
	Germinated	ISC
Dhal	Soaked, boiled with spices	ISC
Flour (besan)	Batter for fried vegetables	ISC
	Batter with rice, fermented	ISC
	Thickener for gravies	ISC
	Fried extrusion products	ISC
	Mixed with wheat flour, bread	ISC, Middle East

generally low in antinutritional factors such as protease and amylase inhibitors, whose activities are further reduced by cooking, and protein-binding phenolics, which are largely removed with processing.

Uses and Processing

Chickpea is a key dietary component in many countries where animal protein is too expensive, or in other countries where the crop has a long history of cultivation and consumption. The complementarity of pulse and cereal proteins has given rise to many traditional dishes in which chickpea is combined with wheat, rice, or some locally important cereal, such as tef, to provide the bulk of dietary protein and calories.

The use of chickpea as human food is hugely varied, reflecting both the crop's antiquity and its broad cultural base (Table 2). The mature seed, either whole or processed, accounts for nearly all consumption. However, there are specialty uses for the green, immature plant. Fully podded plants are commonly sold in street markets in India and the Middle East. The seeds are either roasted in the pod, consumed raw as a snack or boiled; fresh leaves are also used as a vegetable. Ripe seeds (desi and kabuli) are presoaked and boiled, with or without the addition of vegetables or meat, to produce a range of traditional dishes. Kabuli seeds are also canned after cooking, but a more important use is as hommos bitihneh (pureed and mixed with oil). Both desi and kabuli seeds are also roasted. This process generally requires a quick soaking followed by high-temperature treatment (e.g., at 250°C) for 2–3 min in preheated sand or an oven. Variations to the soaking, roasting, and final processing (e.g., decortication, polishing, sugar coating) give this snack food its regional characteristics.

Figure 5 Dhal produced from desi seeds following removal of the seedcoat and separation of the cotyledons.

Most desi seeds are milled to produce dhal, a process that involves removal of the seedcoat and cleaving of the cotyledons (Figure 5). Milling of chickpeas is a major industry in the Indian subcontinent and the newer high-throughput mills achieve a dhal yield close to the theoretical maximum of 83–85%. Dhal is the main form of consumption in the Indian subcontinent; the prepared dish, also called "dhal," is almost always part of the main meal. The third main use of chickpea is as "besan," the flour milled from dhal. (Small kabuli seeds have recently been substituted to produce a cheaper, but inferior product.) Besan is used for a range of purposes, most commonly as a batter or to produce fried, extrusion products.

Chickpea also plays an important, if secondary, role in animal nutrition. In Mexico desi types are grown specifically for inclusion in pig rations. Elsewhere residues from processing (seedcoat and kibble

from milling, damaged or undersized seeds from grading) are routinely used in intensive livestock production. Residues from harvest (stems, leaves, pods, and seeds) are also a valuable feed source for ruminant animals.

Genetic Improvement

Worldwide there has only been a limited breeding effort in chickpea compared to the major cereals and oilseeds. Primitive landraces still account for much of the crop area in developing countries despite the new varieties being released by national programs and the major international centers ICRISAT (India) and ICARDA (Syria). Major breakthroughs have been achieved in developing resistance to the major diseases ascochyta and fusarium. Cold tolerance, coupled with ascochyta resistance, has been deployed in new varieties that enable winter sowing in traditional spring-sowing areas and early maturing varieties, providing some escape from drought, have facilitated the wider adoption of chickpeas in central and southern India. Mechanization of harvest has been facilitated by the development of erect plant types which grow up to 1 m tall and have stronger, more lodging resistant branches than the traditional semi-erect forms.

There is a paucity of genes for many economically important traits in *C. arietinum*, presumably as a consequence of the genetic "bottleneck" caused by domestication. However, genes conferring improved resistance to many biotic stresses, such as bruchids, cyst nematode, and phytophthora root rot, can be found in either or both the closely related "wild" species *C. reticulatum* and *C. echinospermum*. Breeding programs are now employing backcross programs to incorporate a range of attributes from these species into adapted backgrounds. Introgression of genes from unrelated taxa has also been achieved by Agrobacterium- mediated transformation. "Transformed" plants containing genes with the potential to confer improved protein quality and insect and disease resistance have been developed and await field evaluation.

Introduction

Chickpea (*Cicer arietinum* L.) is an ancient crop first taken into cultivation by Neolithic farmers. Today, chickpea continues to play an important role in agricultural systems in the world, ranking third

behind dry bean (*Phaseolus vulgaris* L.) and field pea (*Pisum sativum* L.) in terms of grain legume production. World chickpea production has remained relatively stable since the 1960s, but recently there have been improvements in productivity, and changes in the regions sown to chickpea. World chickpea production was 6.1 million tons (Mt) in 2001 from an area of 8.6 million hectares (Mha). Traditionally, chickpea was grown in India, Iran, Bangladesh, Pakistan, Mexico, and Ethiopia with limited mechanization. Improvements in varieties, agronomy, and production technology and new export market opportunities have seen the expansion of chickpea production in countries such as Turkey, Canada, and Australia. This article summarizes the key constraints to chickpea production and the agronomy of the crop in major production environments.

Adaptation and Production Constraints

Chickpea has broad adaptation, hence the wide geographical distribution of its production. It is considered to be the most drought-resistant, cool-season grain legume and is commonly grown on stored soil moisture or under rainfed conditions, but also responds well to supplemental irrigation in many environments. Chickpea also exhibits a considerable degree of heat tolerance provided there is sufficient soil moisture. Despite its broad adaptation, chickpea production is restricted by several biotic and abiotic stress factors, depending on the environmental conditions under which the crop is grown. Drought, cold, transient waterlogging, soil salinity/sodicity, and high boron in the subsoil are the main abiotic stresses constraining chickpea production. Among the key biotic stresses, a number of diseases and pests can cause serious yield losses. In addition to this, competition from weeds can also result in considerable yield reduction. In recent years, improved varieties and specific agronomic practices have been developed to manage some of the above constraints.

Chickpea Agronomy

Rotational Benefits

Chickpea is often grown in rotation with other crops, mainly cereals, because it reduces the risk of pests and diseases associated with monocropping of cereals and hence increases the production of the entire rotation. An additional benefit is the ability of chickpea to fix atmospheric nitrogen via a symbiotic relationship with rhizobium. Some of this fixed nitrogen and organic matter from roots and nodules are left in the soil in an accessible form, hence reducing the requirement for nitrogen fertilizer in the following crop. In southern Australia, chickpea crops get 37–86% of their total nitrogen through fixation. The amount of nitrogen remaining in the soil after harvest is in the range of 41–56 kg ha^{-1}. Legumes derive only part of their nitrogen through fixation and tend to prefer using soil nitrogen, especially when there is a large amount available. In many instances, more nitrogen is removed than the crop actually fixes, hence the negative values. In these situations, the subsequent cereal crop will still need additional nitrogen fertilizer. However, the non-nitrogen benefits of having a chickpea crop in the rotation may still contribute to increased grain yield and protein contents in wheat (Figure 1).

Soil Type and Land Preparation

Chickpea is successfully grown on a wide range of soil types throughout the world, ranging from coarse-textured sands to fine-textured black soils. Ideally, chickpea is most suited to deep, neutral to alkaline, fine-textured soils (sandy loams, clay loams, and well-drained clays) with a pH of 5.5–9.0 (measured in calcium chloride – $CaCl_2$) and good water-holding capacity. Chickpea is sensitive to waterlogging and sodicity; therefore, soils must have a good structure or a slope that allows drainage. Moreover, chickpea is relatively sensitive to salinity and boron toxicity, and

areas where these conditions occur also need to be avoided.

Chickpea has a slow early growth and competes poorly with weeds. Because options for the control of especially broad-leafed weeds in chickpea crops remain limited, land with low weed burden is desirable. These occur generally after a well-managed cereal crop. Choosing a relatively even land surface with few obstacles is desirable for improving the efficiency of mechanical harvest.

Time of Sowing

Moisture availability, temperature, and photoperiod are the main environmental factors affecting chickpea germination, growth, flowering, podding, and seed set. Chickpea is a long day plant, which is susceptible to extreme temperatures and moisture stress, especially at flowering. Flowering is generally more affected by temperature than by day-length. As a result, the optimal time of sowing will vary depending on the geographical region (Table 1) and sowing too early or too late will lead to reduced crop yields.

In the West Asia and North Africa (WANA) region (except in Pakistan, Egypt, and Sudan where chickpea is sown in winter), chickpea is traditionally sown in spring and grown on stored soil moisture from winter rains. The productivity of this type of cropping system is constrained by drought and heat stress during the grain-filling stage, partly because a large amount of stored soil moisture is lost before sowing. One way to deal with this problem is to develop genotypes that are drought-resistant. Alternatively, these areas need to change their cropping system from spring-sowing to winter-sowing. However, a move to winter sowing requires improved disease resistance and winterhardiness, because fungal infections are likely to increase and the cold temperatures lead to seedling death or during flowering may result in flower and pod abortion. Advancing the chickpea-sowing date has led to yield increases of more than 100% in some regions due to longer crop-growth periods and increased water use (Table 2 and Figure 2). In the Mediterranean-type environments of southern Australia, chickpeas are generally sown after the first autumn rains and grow on winter rainfall. The autumn-sown chickpea crops yield more seed than the winter-grown ones. In the semiarid Canadian prairies, chickpea is sown early in the spring growing season when soil moisture is still high.

In the northern hemisphere tropics, including South Asia, Africa, and Central America, the best crop performance is realized when chickpea is sown in the cooler part of the year after the rain season on stored soil moisture. An early sowing can lead to seedling mortality as a result of high soil temperature whereas sowing too late may inhibit germination because of insufficient soil moisture. In the northeastern part of Australia, chickpea is sown in May or June on stored soil moisture from summer rainfall.

Table 1 Time of sowing and harvest of chickpea in various producing regions

Country	*Season*	*Sowing time*	*Harvest*
Morocco	Spring	Mid-Feb./mid-Mar.	June to early July
Tunisia	Spring	Mid-Mar./mid-Apr. small areas of winter sowing	June to early July

Indian subcontinent	33	40–65	30–45
Canada	45	120–150	25
USA	40	90–125	30
Turkey	35	90–120	25
Tunisia	20	70–90	70–100

Sowing Rate, Depth, and Method

Plant density controls establishment success, yield, and ultimately, the profitability of a crop and is determined by the sowing rate and germination percentage. Inadequate plant stand is one of the most common yield retardants in many production areas in the world.

Chickpea sowing rates vary between 40 and 200 kg ha^{-1}, depending on the genotype used, seed size, and the environmental conditions (Table 3). On an average, a plant density of 33 plants m^{-2} has been found to produce optimum seed yields across a range of environments. However, this density can be increased in favorable soil conditions and should be reduced under marginal conditions. Sowing rates are higher for "kabuli" type than for "desi" type chickpea because they have larger seeds. In addition to this, the thin seedcoat of kabuli makes the seeds more susceptible to mechanical damage during harvest and handling which results in a lower germination percentage. In addition to this, the seedcoat of kabuli lacks the phenolic compounds that reduce fungal attack, which can lead to reduced germination in the absence of seed-dressing fungicide. The plant density producing the maximum yield is not always the most profitable and hence an economically optimum plant density needs to be determined (Figure 3).

In India and Africa, chickpeas are traditionally sown in wide rows up to 150 cm to facilitate manual weed control and also, in developed countries, a row spacing of 70–100 cm are used to allow mechanical inter-row cultivation. However, this wide spacing often leads to low plant densities and low seed yields and in Mediterranean-type environments it can lead to excessive soil moisture loss through evaporation. Generally, a close row spacing of 18–35 cm has been found to be most productive.

The optimum sowing depth for irrigated chickpea or chickpea grown in high soil-moisture conditions

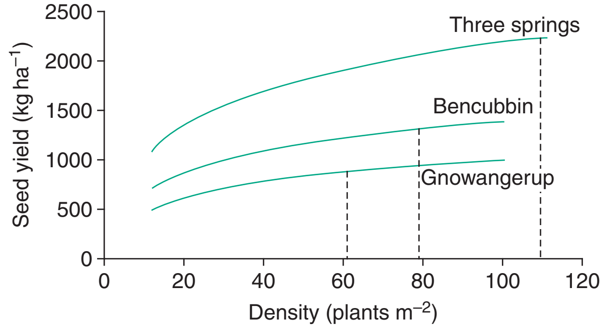

Figure 3 Relationship between plant density and grain yield at typical high, medium, and low yielding sites in Western Australia. Dotted lines indicate the estimated optimum plant density. (Reproduced with permission from Jettner RJ, Siddique KHM, Loss SP, and French RJ (1999) Optimum plant density of desi chickpea (*Cicer arietinum* L.) increases with increasing yield potential in south-western Australia. *Australian Journal of Agricultural Research* 50: 1017–1025.)

varies between 5 and 8 cm but can increase to 10–15 cm in moisture-deficient soils without affecting emergence and yield (Figure 4). Deep sowing is beneficial for crops grown on stored soil moisture in dry areas with high temperatures and soil-evaporation rates. Moreover, deep sowing protects the crop from pre-emergence herbicide damage, frost, wind and insect attacks, and improves survival of rhizobium bacteria inoculated on the seed. It is likely that an interaction exists between seed size and sowing depth in chickpea, but this deserves further research.

Greater seedling emergence can be realized with mechanical sowing methods (drills, precision seeders) than seeding by hand. The sowing process is fully mechanized in North America, Australia, and most parts of Turkey and Europe. It is still broadcast or drilled using local implements in many regions of WANA and the Indian subcontinent.

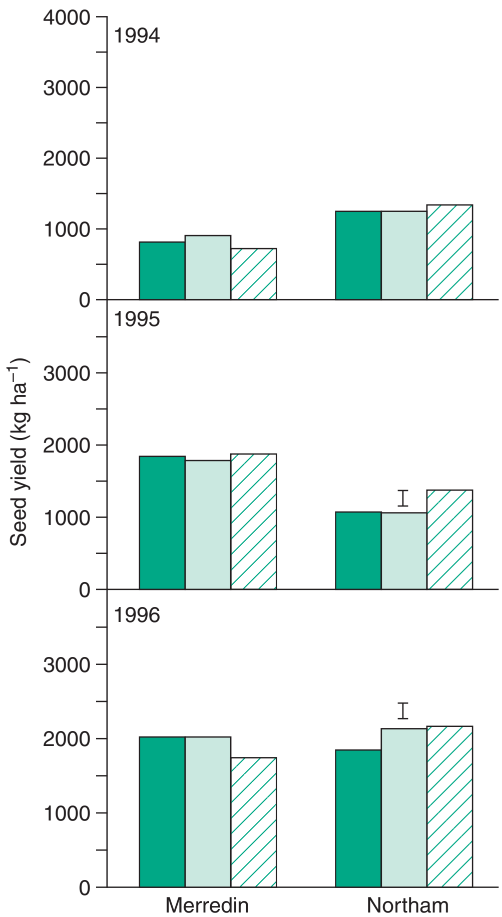

Figure 4 Seed yield of chickpea sown at 2.5 (solid green), 5.0 (light green), and 10.0 cm (hatched) at Merredin and Northam, Western Australia. Vertical bars denote l.s.d. ($P = 0.05$) where differences are significant. (Reproduced with permission from Siddique KHM and Loss SP (1999) Studies on sowing depth for chickpea (*Cicer arietinum* L.), faba bean (*Vicia faba* L.) and lentil (*Lens culinaris* Medik) in a Mediterranean-type environment of south-western Australia. *Journal of Agronomy and Crop Science* 182: 105–112.)

Inoculation and Nitrogen

Being a legume, chickpea is capable of fixing atmospheric nitrogen through its symbiotic nodules formed upon infection with the nitrogen-fixing rhizobium bacteria. These bacteria, however, are species-specific and survive poorly on acidic coarse-textured soils. Therefore, inoculation of seed with rhizobium is needed for successful establishment of chickpea in marginal soil conditions and on fields that have not grown chickpea in the past.

Due to the symbiotic relationship with nitrogen-fixing bacteria, chickpea is able to survive on soils with low nitrogen levels. However, the rhizobium bacteria need 6–8 weeks to form the root nodules and commence nitrogen fixation. The seedling growth depends upon seed-source nitrogen in the initial periods and seed reserves of nitrogen tend to run out before the commencement of nitrogen fixation. In nitrogen-poor soils, therefore, a small starter dose of nitrogen (10–25 kg N ha^{-1}) can stimulate root and shoot growth during early crop development and lead to increased seed yields. Once the root nodules are active, no yield increase is observed upon addition of nitrogen fertilizer.

Other Nutrient Requirements

In contrast to cereal plants that take up almost all the phosphorus in their early growth stages, grain

legumes require a continuous supply of phosphorus throughout their entire growing season. Phosphorus deficiency is a widespread problem in South Asia and Africa and application of 60 kg ha^{-1} of P_2O_5 has been shown to increase chickpea yield. However, the response to phosphorus tends to be less in chickpea than in other cool-season food legumes and cereals because chickpeas are able to exploit sources of phosphorus unavailable to most plants. Chickpea roots excrete organic acids that dissolve insoluble phosphorus compounds in the soil. Secretion of organic acids also dissolves insoluble copper, zinc, iron, and manganese, thereby avoiding deficiency of all these nutrients and hence few of these deficiencies have been reported. Iron deficiency, however, is common on high-pH calcareous soils in South Asia and chickpeas respond positively to foliar spray of 0.5–2% $FeSO_4$ solution. More recently, the considerable genetic variation among chickpea genotypes has made it possible to develop cultivars which are tolerant to iron deficiency. The critical zinc concentration in dried shoots is 17–21 mg kg^{-1} and zinc deficiency has been observed in India and southern Australia. Sulfur deficiency is a problem in light textured soils in India and addition of 20 kg ha^{-1} sulfur can increase yield by 0.3–0.6 t ha^{-1}. Application of boron in chickpea leads to increased seed yield in boron-deficient soils of Nepal, Bangladesh, and parts of eastern India. Since soils of most chickpea-growing regions have a high potassium status, potassium deficiencies in chickpea are rare.

Weed Management

As a slow grower, chickpea competes poorly with weeds and therefore good weed-management is critical for high yields and quality. Because there are only limited options for chemical weed-control in chickpea crops after emergence, it is essential to deal with these weeds in the previous crop and before sowing. In developing countries, weeds are controlled mainly through cultural, manual, and mechanical techniques, whereas chemical weed-control methods are mainly used in North America, Canada, and Australia. The most effective chemical weed-control is generally achieved by a presowing application, a postsowing, pre-emergence application, and a post-emergence application of herbicides. There are numerous presowing and postsowing pre-emergence herbicides available for controlling broad-leafed and grass weeds. The most effective and commonly used presowing herbicides are Simazine and Cyanazine at rates of 1–2 l ha^{-1}, whereas Metribuzin^{TM} and Spinnaker^{TM} at 200 ml ha^{-1} are used after sowing and before emergence. Although there are several grass selective post-emergence herbicides, the options for broad-leafed weeds are limited.

Disease and Pest Management

Over 50 diseases are known to affect chickpea worldwide, including *Ascochyta* blight, *Fusarium* wilt, root rots, rust, *Botrytis* gray mold, and viral diseases. From these, *Ascochyta* blight and *Fusarium* wilt are the most important and devastating diseases worldwide, whereas the others are only important on a more regional level. In addition, numerous pest species have been associated with chickpea, including more than 46 species of nematode.

Ascochyta blight is caused by the fungus *Ascochyta rabiei* Pass. (Labr.). The disease was first reported in 1911 in the Indian subcontinent, but since then has been reported in 32 different countries. Changing from spring to winter sowing in Mediterranean region has increased the occurrence of the disease in these areas. The fungus attacks all the aerial parts of the chickpea plant, making it the most destructive of the chickpea diseases and causing yield losses up to 100%. Severe infections with *Ascochyta* blight cannot be controlled by chlorothalonil fungicide and disease management through resistant cultivars is essential. In addition to the use of fungicides (seed dressing and foliar application) and resistant cultivars, cultivation practices such as crop rotations with cereal crops and managing infested debris have contributed to successfully managing *Ascochyta* blight.

The most devastating soil-borne disease of chickpea is *Fusarium* wilt, caused by the fungus *Fusarium oxysporum* Schlecht. emend. Snyd. & Hans. f. sp. *ciceri* [Padwick] Snyd. & Hans. Most chickpea-growing countries have reported the disease, which affects both roots and aerial plant parts and can cause yield losses of 10–50%. Although the disease can be minimized by seed dressings with fungicide (Benlate T at 0.15% rate), it is more economical to use resistant cultivars. Several resistant cultivars have been developed and released but these have not shown resistance across all locations due to area-specific races of the pathogen. Therefore, supplemental management practices like crop rotation are needed to control *Fusarium* wilt infestations.

Only very few of the more than 46 reported nematode species found in association with chickpea cause a severe yield loss in chickpea. The root-knot (*Meloidogyne* spp.), cyst (*Heterodera* spp.), and root-lesion nematodes (*Pratylenchus* spp.) are most damaging to the crop and nematode infections have been reported from all over the world. Proper crop rotations are the most effective and economical ways to control nematode infections, as opposed to the use of

nematicides. The search for nematode-resistance in cultivated chickpea has been unsuccessful and efforts are being made to find nematode-resistance in wild relatives of chickpea and ways to transfer resistance to the cultigen.

Insect pests generally cause less damage and yield loss to chickpea crops than diseases for two reasons. First, chickpea plants excrete organic acids from hairs on their leaves, stems, and pods, which are unpalatable to most crop pests. And second, chickpea is generally grown around winter in most countries when insect activity and populations are very low. This is not the case, however, in the subtropical chickpea-growing regions, where some insect pests pose a real treat to chickpea production. The most damaging insect pests are pod borers (*Helicoverpa* spp.) and leaf miners (*Liriomyza cicerina*). Pod borers occur in all chickpea-growing countries whereas leaf miners are restricted to the WANA region and eastern Europe. Both insects can cause significant reductions in yield and quality, especially pod borer. Spraying with insecticides is economical only when the infestation is serious and when a high yield ($>1\ \mathrm{t\,ha^{-1}}$) is expected. In Australia, pheromone traps specific to pod-borer moths are used to monitor moth flights and adjust timing of insecticide application to minimize damage to crop yield and quality. Moreover, the use of conventional insecticides has declined because insects have developed resistance to these insecticides, and due to possible health and environmental hazards. Alternatives to spraying are biological control (e.g., nuclear polyhedrosis virus kills *Helicoverpa* spp.), cultural control (e.g., advancing sowing date), and host-plant resistance. Efforts are being made to develop chickpea cultivars that combine insect-resistance, disease-resistance, and high yield.

Bruchids (*Callosobruchus* spp.) are the main insects attacking stored chickpea seed and have been reported from all chickpea-producing countries, particularly from the Indian subcontinent. Such infestations can damage up to 70% of the seeds. An effective way to avoid bruchid damage is harvesting soon after the crop is mature and storing seed in insect-proof containers. This method is preferred to treating the stored seed with fumigants (e.g., phostoxin) or insecticides (e.g., malathion). No useful bruchid-resistant chickpea genotypes have been identified so far.

Water Use

Chickpea is considered to be the most drought-tolerant, cool-season grain legume. It has the greatest ability to tolerate intermittent drought and respond to subsequent rainfall due to its more indeterminate growth habit. However, seed-yield loss due to terminal drought can be as high as 60%. To avoid drought conditions, chickpea is generally grown during or just after the rain period on stored soil moisture. However, the crop sometimes faces mild to severe terminal drought during flowering and seed filling, which are the most drought-sensitive stages. Low soil moisture can cause abortion of flowers, immature pods, and developing seeds and hence considerably reduce seed yield. Recent studies in southern Australia have shown water-use efficiencies for dry-matter production between 11 and $18\ \mathrm{kg\,ha^{-1}\,mm^{-1}}$ and water-use efficiencies for grain yield between 2.6 and $7.7\ \mathrm{kg\,ha^{-1}\,mm^{-1}}$. This study also showed chickpea to be less water-use efficient than the high-yielding faba bean and field pea (WUE_{dm}: $19-39\ \mathrm{kg\,ha^{-1}\,mm^{-1}}$ and WUE_{gr}: $6-16\ \mathrm{kg\,ha^{-1}\,mm^{-1}}$) crops that escape terminal drought by vigorous early growth, early flowering and pod set, and rapid seed fill at maturity. Increasing early growth for rapid ground cover and reduced soil evaporation, and tolerance to cold temperatures during flowering and pod setting are essential to improve water use efficiency of chickpea in Mediterranean-type environments. Selecting genotypes with larger root systems, early flowering and pod setting, increased osmoregulation or greater translocation of biomass from stems and leaves to seed are other strategies explored by chickpea breeders for improving yield potential.

In areas where annual rainfall is less than 400 mm or where there is a risk of drought during the late vegetative and reproductive stages, chickpea responds positively to supplemental irrigation. Supplemental irrigation in Egypt, Israel, Lebanon, Mexico, and Central Queensland (Australia) has helped the realization of higher yields. Mexico has the highest yield in the world, a reflection of the irrigated conditions in which the crop is grown in that country. In the Ord River Irrigation District in northern Western Australia, chickpea is grown during the dry winter and relies fully on irrigation.

Harvesting and Storage

Harvest and storage have a significant impact on the quality of chickpea grain. Chickpea is ready to harvest when stems and pods start yellowing and the seed moisture content is $\sim$15%. When harvest is delayed beyond this point, the seed moisture content decreases and the seed becomes susceptible to cracking. Moreover, it increases crop lodging and pod shedding. Early harvesting of the chickpea crop has been shown to increase yield up to 30% when suitable drying facilities are available.

In developing countries, most of the harvesting and threshing is still done by hand, a time-consuming and

expensive process. In Australia, Canada, the USA, and most parts of Europe, harvesting is completely mechanized. Generally, a maximum harvesting speed of 8 kmph and a low cutting height of 10–15 cm is used, but harvester settings vary depending on the conditions. Crop desiccation before harvesting is a valuable tool for easier harvesting when a lot of maturing weeds are present. However, desiccant can only be applied when more than 90% of the crop reached physiological maturity to prevent yield reductions.

Seed quality deteriorates rapidly with storage and reducing moisture and temperature increases longevity of the seed. Storing seed at less than 13% moisture, however, has adverse effects on the viability because it makes the seed shrink away from the seedcoat. Therefore, reducing the storage temperature to 20°C is the best option for increasing seed longevity.

Marketing and Quality

Being a good source of carbohydrate and protein, chickpea is traded for human consumption in both developing and developed countries, and to a limited extent as stock feed. Most of the world's chickpea seed is consumed close to the place where it is grown. However, a large number of chickpea-producing countries are unable to meet local demand and need to import. India is the world's largest producer, consumer, and importer of chickpea. The main exporters of chickpea are Turkey, Canada, Australia, and Mexico with main markets in India, Pakistan, Bangladesh, Europe, USA, Middle East, and the former USSR.

Visual grain quality is becoming increasingly important when marketing chickpea and is affected by characteristics like seed size and shape, seed color, insect damage, and amount of split, chipped, broken, and foreign seeds. Other quality parameters like cooking time, and splitting and milling recoveries are also important to chickpea consumers and processors. Good crop-management practices are essential to produce high-quality seed and at the same time result in high yields.

Future Prospects

New chickpea varieties with greater resistance to key biotic and abiotic stresses are currently being developed by various national and international agricultural research organizations. Development of variety-specific agronomy packages and immediate transfer of such production technology to farmers will further increase sustainable production of this important cool-season food legume.

COOKIES, BISCUITS, AND CRACKERS

Contents

Methods of Manufacture

L Doescher Miller, Formerly of The Pillsbury Company, Minneapolis, MN, USA
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

A few generations ago, biscuits and cookies were most familiar as items that came from the home oven. More recently, they are commonly the product of factory manufacture, reaching the home in a packet. Nevertheless, the methodology of production (in home or factory) is similar, involving the essential steps of mixing, shaping and forming, and baking. Obviously, there are major differences in detail involved in the mass-production process, compared to making a small batch of cookies at home. This article describes the processes used to produce the diversity of cookies/biscuits and crackers that reach us in packets, following these three major steps–mixing, forming, and baking.

Mixing

The first step in manufacture involves the blending of the ingredients into a uniform, homogeneous mixture. In the context of cookie and cracker doughs, the term "mixing" takes on a broader meaning in that it also applies to the development of gluten from hydrated flour proteins, the aeration of a mass to give a lower density, and the dispersion of solids in liquids. One or more of the functions are required for the formation of cookie and cracker doughs. These processes are accomplished with three principal types of mixers: vertical spindle mixers, horizontal drum mixers, and continuous mixers.

Vertical Spindle Mixers

Vertical mixers were used extensively before the development of the high-speed mixer. Although usage has decreased overall, this type of mixer is still used for crackers and semisweet doughs, for which the vertical spindle design is particularly well suited. The feature that all vertical mixers have in common is the portable dough trough, which serves as the mixing vessel. The trough is usually a wheel-mounted, heavy tub with vertical sides, round ends, and a flat bottom. The trough is designed so that it may be wheeled into position below the mixer head and locked into place. Mounted on an overhead frame are the drive mechanism and spindles with horizontal paddles or arms. Most mixers of this type are equipped with two or three spindles. The spindles are lowered into the trough and move in either a planetary or a stationary, circular motion when activated. The shape of the arms forces the dough upwards and downwards in the trough, generating

a mixing action. The mixer blades are designed to provide a cutting action rather than kneading or stretching the dough.

The advantage of vertical spindle mixers is that they can be used for almost any product. They are very well suited for products such as soda cracker doughs. These doughs require a two-stage mixing sequence separated by a fermentation period. The sponges and doughs do not have to be transferred in and out of the trough at each mixing stage. Instead, they remain in the same trough for the entire mixing/fermentation sequence. Because there is almost no heat generated during the mixing process, this mixer is ideal for doughs that must remain cool. The mixing action is very gentle. Doughs containing ingredients or particulates that are easily damaged may be safely mixed with this mixer type.

The primary disadvantage of vertical mixers is their slow operating speed. The spindles rotate over a limited range at two or three speeds, up to a maximum of ~20 rpm. For doughs requiring the development of a gluten network, the mixing time required may be as long as 90 min. Because this is slow relative to the speed of the remainder of the processing line, several mixers may be needed to maintain an uninterrupted dough supply. Other disadvantages include lack of uniformity of the mix, and the labor-intensive nature of the system's design. The latter disadvantage relates to the fact that the dough troughs are very heavy, requiring special equipment to move, lift, and tilt the tubs at each stage of the process.

Horizontal Mixers

The feature that all mixers of this type have in common is a horizontal bowl mounted on a rigid frame that encloses the drive motor. The bowl may be stationary with a vertical front wall that slides down so that the dough may be ejected. More commonly, the mixer bowl is designed to tilt, and the dough is ejected from the tilted position. In both designs, the top cover is fixed so that mixing takes place in an enclosed space.

The blades of horizontal mixers are mounted on a horizontal shaft and may have any of several different shapes, depending on whether a cutting, scraping, or kneading action is needed. Mixing times for cookie and cracker doughs range from 5 min for soft doughs to 30 min for the hard doughs, which require gluten development. Most mixers of this type are fitted with a jacket surrounding the mixing chamber. This allows a coolant to be circulated, so that dough temperatures can be controlled. Without such control, horizontal mixers can increase the dough temperatures to the point where dough handling and finished product properties are adversely affected.

The advantages of horizontal mixers are their high speed, ability to supply dough to a processing line continuously, uniformity of the mixes they produce, and their potential for complete automation. Horizontal mixers may be operated at speeds of 15–80 rpm. Commonly, their power train is equipped for two-speed rotation. Unlike most vertical spindle mixers, ingredients may be added with the blades in motion, and the discharge of the dough from the mixer is simple. Accurate control of dough temperature is possible, because there is a continuously circulating refrigerant.

Horizontal mixers require that all ingredient-charging spouts be located overhead or that ingredients be added manually. Charging the mixer with ingredients is typically a significant portion of the total mixing cycle time. During mixing, the blades may throw material to the top of the chamber, so that it is never fully incorporated. With the shaft and mixing blades located in the center of the bowl, dough discharge is not always rapid and may occur in several large fragments. Only one operation (charging, mixing, or discharging) may be performed at any one time, so that fast cycling of the dough batches may not be possible.

Horizontal mixers usually have capacities of up to 550 kg. The weight and the vibrations generated by their relatively high operating speeds place special design demands on the production facility. In addition to a reinforced floor, special mounts are necessary to secure the mixer in place.

Continuous Mixers

Continuous mixers are best described as a rotor- or screw-operating within a barrel jacketed for temperature control. The ingredients are fed continuously, either from one end of the barrel or in successive ports at intervals along its length. The mixing action may be altered from gentle blending and dispersing to vigorous or high-intensity kneading by varying the arrangement of different mixing arms along the length of the barrel. The amount of work put into the dough during its transit may be controlled additionally by restricting the dimension of the outlet orifice, creating a back pressure inside the barrel.

Continuous mixers are favored in some plants because they are capable of providing a constant supply of dough to the production line. Continuous mixers are small in size relative to horizontal mixers and are suitable for complete automation. In spite of this advantage, continuous mixers are not common in cookie or cracker plants, where a single line may be required to produce a variety of products. They are usually

used only on high-output lines having a single purpose or similar product types.

The primary disadvantages of this mixer type are its high cost and the additional cost of the associated automated, continuous ingredient-feeding systems. Beyond this, continuous mix systems are not particularly flexible; different products usually require completely different types of machines. In addition, the initial process set-up can be difficult, requiring considerable experimentation to determine optimum mixing conditions and sequences. Finally, starting and stopping the process are difficult in the event of any problem along the rest of the production line.

The Forming Process

This step is specific to each product type, whereas the mixing and baking stages may be similar for all types of products. Three processes are used to form cookie and cracker doughs: (1) cutting or stamping from a continuous sheet of dough, (2) rotary molding by shaping dough in die cavities cut into the surface of a metal cylinder, and (3) extruding dough through a shaped die.

For each of these methods, the rheology of the dough is different and is designed to be compatible with the process. In general, doughs that are to be sheeted possess a significant gluten network as a result of mixing, and are both elastic and extensible. Those destined for rotary molding lack gluten development and are best described as cohesive. Doughs intended for extrusion are soft, frequently high in shortening, and spread while baking.

Sheeting and Cutting

The most common and versatile method to form cookie and cracker doughs is sheeting and cutting. This method involves the production of a thick sheet of dough, evenly reducing the thickness of the sheet, cutting out the desired shapes, and returning the scrap dough to be reincorporated either in the mixer or early in the sheeting process. This method is used for the production of crackers, semisweet biscuits, and selected soft doughs.

After mixing, the dough is fed into a hopper, below which lie the sheeting rollers. There are typically three rollers below the hopper arranged in a triangular fashion (Figure 1). At least one of the top two rollers, known as forcing rollers (labeled A in the figure), is grooved so that a positive feed is provided to the gauge or gauging roller. The gauging roller (B), which is always smooth, serves to deliver the dough to the conveyor belt (C). The purpose of the sheeting unit is to compact the mass from dough hopper uniformly and provide a sheet of even thickness having the width of the processing line.

The relatively thick dough slab from the sheeter then passes through a series of reduction or gauge rollers (D). These are smooth steel rollers used to reduce the dough sheet to the thickness that is desired before cutting of the finished dough piece. The gauge rollers occur in pairs mounted vertically. For products having sticky or adherent doughs, it may be necessary to mount a scraper blade against one or both of the rollers to release the sheet of dough. On most process lines, there are two or three pairs of rollers. This ensures that the thickness is reduced no more than 50% at any one rolling operation.

Some doughs, such as those of saltines and cream crackers, are laminated before cutting. The lamination occurs by lapping the dough back upon itself in the process direction. At the lapper, the take-away conveyor lies at a 90° angle relative to the line delivering the dough. The number of layers is controlled by the relative rate of the lapper and take-away conveyor. The lapped dough then passes through several more sets of gauging rollers to bring the dough sheet to the desired thickness prior to cutting.

The repeated working of the dough in one direction results in the accumulation of stress. If the dough were cut at this point, the resulting pieces would shrink to

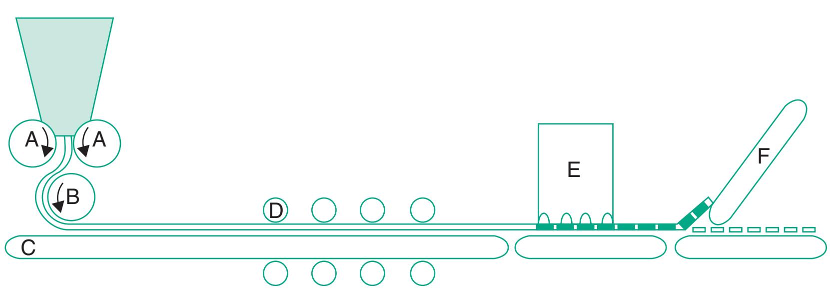

Figure 1 Sheeting and cutting process. See text for explanation. (Reproduced from Macrae R, Robinson RK, and Sadler MJ (eds.) (1993) Biscuits, Cookies and Crackers: Methods of Manufacture. In: *Encyclopaedia of Food Science, Food Technology and Nutrition*. Academic Press.)

relieve the stress, and misshapen or distorted products would result. Therefore, it is normal to relax the dough after reduction and before cutting. The relaxation is accomplished by transferring the dough to a conveyor, still moving in the same direction, but at a slower speed.

Once the dough has been relaxed, it passes on to the cutting operation. Two different types of cutting methods exist: reciprocating cutters and rotary cutters. The reciprocating cutters are heavy block cutters that stamp out one or more pieces at a time. The cutter head (E) may have a dual action, whereby the cutter drops first, followed by a docking head or an embossing plate. The equipment operates via a swinging mechanism so that the dough sheet moves at a constant speed, the cutter drops and moves with the dough, and then rises and swings back to the original position. The second type of cutter, the rotary cutter, consists of a rotating metal cylinder. On the face of the roll are formed the desired shapes with a sharp metal edge. As the cutter rotates with the dough conveyor, the metal edges cut into the dough sheet to form the product. The product pieces are then conveyed into the oven.

As a result of either cutting process, 20–60% of the dough sheet remains as scrap. The scrap dough (F) is lifted away from the cut dough pieces and returned either to the mixer or to the sheeter. Return to the mixer permits uniform incorporation of the scrap into the dough mass. However, most systems route the scrap back into the sheeter either along the full length of the hopper or at the back side of the hopper. If dough is incorporated behind the new dough, imperfections will be on the bottom side of the dough sheet and will not be visible on the finished product.

Rotary Molding

The principle of rotary molding is illustrated in Figure 2. Three rollers are placed in a triangular arrangement below a dough hopper. A roller, called the forcing or feed roller (A), has deep grooves designed to pull dough down from the hopper. The dough is forced into the cavities of the engraved roller (B) by the forcing roller. A scraper blade (C) is mounted against the engraved roller to remove any excess dough and return it to the hopper via the forcing roller. Beneath the engraved roller is a rubber-covered extraction roller (D) that serves to drive the take-away belt (E). The extraction roller applies pressure to the engraved roller via the belt, causing the dough to adhere preferentially to the conveyor belt. Dough pieces are dropped from the take-away belt into pans or directly on to the baking belt (F).

The rotary molding process is suitable only for dry, crumbly doughs. This process offers advantages over sheeting and cutting in that there is no scrap to recycle, and there are very low labor requirements to run the process.

Extrusion

There are two types of devices used in the production of extruded cookies: wire-cut machines and bar/rout-presses. Both systems are very similar in design (Figure 3). A hopper is placed over a system of two or three rollers (A) that force dough into a pressure chamber (B). The rollers may run continuously or intermittently to force dough out of the pressure chamber at the die. For wire-cut cookies, the dough is extruded through a row of dies, and a wire or blade (C) mounted on a frame moves through the dough just below the die nozzle outlet. The cut dough pieces then drop into a conveyor band (D) for transport to the oven. The wire usually moves only in one direction through the dough, opposite that of the conveyor. The wire-cut machines operate at rates of up to 100 strokes per minute. Difficulties encountered with this type of production are distortion of the extruded

dough piece during cutting, and inconsistent placement or drop of the cut piece on to the conveyor.

The design of the bar- or rout-press is very similar to that of the wire-cut machine. The hopper rollers and pressure chamber are essentially identical to their wire-cut counterparts. Unlike the wire-cut machine, the base of the pressure chamber has a die plate that is inclined in the direction of the extrusion. A continuous ribbon of dough is extruded from a nozzle, which is shaped to impart the desired finished product design. The dough ribbon can be cut into individual pieces by a vertically operating guillotine before the oven or after baking. If the product can be baked as a continuous ribbon the dough is extruded directly on to the oven band; otherwise, it is extruded and cut on to a conveyor belt.

Baking

The baking of cookies, biscuits, and crackers is performed almost exclusively in band or traveling ovens. The band oven is essentially an insulated, heated tunnel equipped with a continuous conveyor. The ovens vary both in length (from 30 to 150 m) and in band width (from 1.0 to 1.5 m). More modern ovens frequently consist of a series of modular units or zones. Each of the zones is equipped with its own set of controls so that the temperature and air flow may be controlled within that zone. The oven band is typically continuous, passing on to a drive drum at the end of the oven and returning underneath the baking chamber to a tension drum at the feed or input end of the oven. The chamber through which the oven belt returns may or may not be enclosed. Frequently, the oven band serves as the baking surface for the product. Depending on the product type, the oven band may be solid or any of a variety of open wire-mesh types. The choice of mesh is a critical factor in the process, as it affects the heat transfer at the bottom of the product. This, in turn, can have a marked effect on the quality of the finished product.

There are three basic types of ovens: direct fired, indirect fired, and fully indirect fired. Ovens are usually heated by the combustion of gas, although there are a few manufacturers who use oil or electricity for economic reasons. The most common type is the direct-fired oven, in which gas is burned inside the baking chamber itself. In these ovens, the burners are placed across the width of the oven at regular intervals, both above and below the oven band. In other oven types, termed "indirect ovens," the gas or oil is burned outside the baking chamber, and the heated combustion gases are circulated into and throughout the baking chamber. Indirect-fired ovens typically have a single burner for each section. The hot gases from the burner pass along pipes parallel to the length of the oven, both above and below the oven band. The products of combustion are circulated throughout the baking chamber by large fans. Fully indirect ovens are those in which the heat source is independent from the baking chamber and heat transfer occurs via a heat exchanger. None of the products of combustion circulate inside the baking chamber. This type of oven is not common, except when oil is used as a combustible material. If circulated, the products of this type of combustion would impart an unacceptable flavor to the products.

Cooling

Products hot from the oven must be cooled prior to packaging for several reasons: the products may not be firm enough to withstand the packaging process while warm, the packaging material may shrink around a warm product, or the quality of the products would deteriorate if palletized while warm because the cooling rate across the pallet would be quite slow.

The normal method of cooling products is to place them on an open conveyor and transfer them along a distance 1.5–2 times the length of the oven. The products cool naturally in the ambient factory atmosphere. In a few cases, it is necessary to provide forced air to aid the cooling process.

Wafers

K Tiefenbacher, Vienna, Austria
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

The ice cream cone is the most familiar member of the wafer product group. Like many uses of wafers, the ice cream cone is the ultimate illustration of the concept of providing food in an edible container. Indeed, wafers usually serve the function of being edible carriers of an added food. However, the crispness of the wafer enhances the appeal of the added food, making the wafer much more than an inert carrier.

Wafers are a special member of the biscuit/cookie/cracker family of cereal products. The diversity of wafer shapes (illustrated in Figure 1) includes flat wafers, hollow wafers, molded cones, rolled wafer cones, and wafer sticks. Wafers are thin, crisp, and precisely shaped products, generally made from cereals. They may be made from quite different recipes, using a diversity of manufacturing equipment, and destined for a variety of uses. However, they share the same fundamental sequence of manufacturing steps detailed in this article. To understand the manufacturing process, the concepts of water activity, and glass transition are of critical importance.

The Main Features of Wafers

Wafers are baked as sheets, cones, and sticks or with different fancy shapes. The characteristic features with respect to other bakery products are:

1. Wafers are very thin biscuits; the overall thickness is usually between less than 1 and 5 mm. They often have a typical "wafer pattern" on one surface or on both. The surfaces are smooth and precisely formed, with the dimensions and all the details – engravings, logos, etc. – of the baking molds. See Figure 1 for some examples.
2. Wafers are cereal-based low-fat products made of wheat flour, sometimes with addition of other flours or starches. The product density is in the range of 0.10–0.25 g cm^{-3}. In cross-section, the wafer matrix is highly aerated and primarily of gelatinized starch.
3. Wafers, by their typical delicate and crisp texture, combine well with different fillings (cream, ice cream, foam) and coatings.

There is sometimes confusion in terminology between the crisp "wafers" as described here and "waffles,"

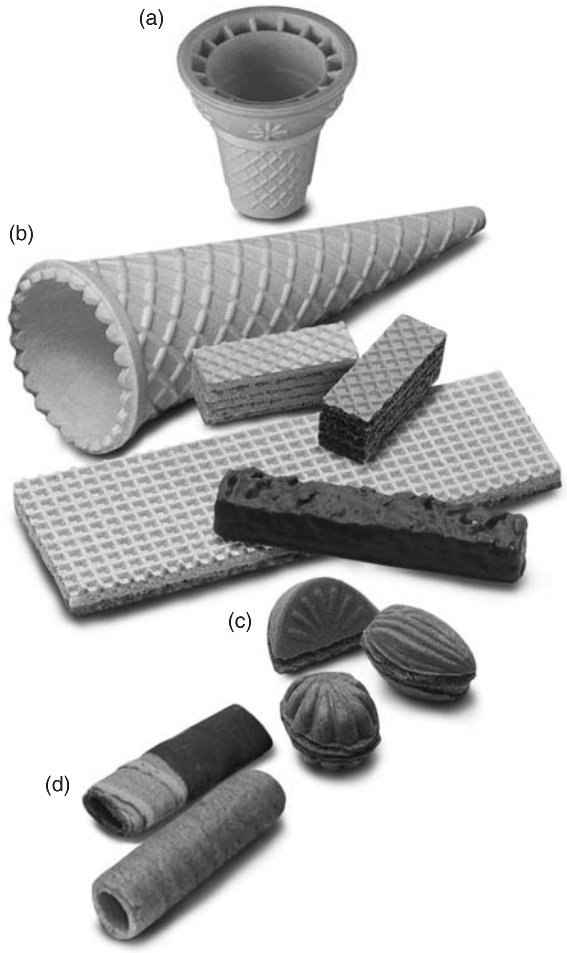

Figure 1 Wafer products. *From top to bottom*: (a) molded cones; (b) flat wafers, creamed/enrobed; (c) hollow wafer pieces; and (d) wafer sticks. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 539, Elsevier Ltd.)

which are of a soft, cake-like texture but show some kind of wafer pattern, too.

The Main Types of Wafers

There are two basic types of wafers:

1. *No- or low-sugar wafers*. After baking, these contain from zero to a very low percentage of sucrose or other sugars. Typical products are flat and hollow wafer sheets, molded cones, cups, and fancy shapes.
2. *Higher-sugar wafers*. Well over 10% of sucrose or other sugars are responsible for the plasticity of the hot, freshly baked sheets. These are formed into different shapes before sugar recrystallization occurs. Typical products are rolled sugar cones, rolled wafer sticks or tubes, and deep-formed fancy shapes.

As in both wafer types, the main ingredient is flour, wafers fit very well into current dietary recommendations to consume more cereals. They are high-carbohydrate, low-fat products.

The baking of "wafers" between hot metal plates has been known since medieval times, but these first wafers were more similar to our waffles or pancakes in their high fat and egg contents and their texture.

Modern wafers are low-fat cereal products, very similar to the altar breads for Christian churches, and are basically made out of flour and water. The first wafer ovens were used after First World War, but more automatic manufacturing lines have been available since the mid-1950s.

The Main Recipes for Wafers

There are two questions to be answered before deciding upon a wafer recipe:

1. What is the end use of the wafer? If it is part of a cream-filled, chocolate-covered biscuit, where contributing a crisp texture element is far more important than the taste of the wafer itself, recipes with few components are recommended. If the wafers are consumed directly as wafer bread or wafer sticks, more sophisticated recipes are chosen.
2. What kind and quality of raw materials are available? Low- to medium-protein soft wheat flours with a low water absorption work best, especially for no-sugar wafers. Problems with suboptimal flours must be balanced by variations in minor ingredients in the recipe. The use of wholemeal flour is possible, and in some regions, other cereals such as rice or corn are used for wafer production.

Table 1 lists the common ingredient ranges for both types of wafer.

In-line Manufacturing of Wafer Biscuits

Wafer biscuits are the most important products by volume. The different steps of manufacture are illustrated in Figure 2.

Batter Preparation

Wafers are made from a fluid batter with a typical viscosity in the range of 300–2000 mPs. First, the water-soluble components are dissolved. By adding the farinaceous ingredients, a homogenous suspension, the "wafer batter," is obtained within a few minutes of mixing (Figure 2, process 1).

Batter Transport and Depositing

From an intermediate tank via a ring main, the batter is pumped to the oven and spread on to the baking molds by a depositor head (Figure 2, process 2).

Wafer Sheet Baking

The baking of wafer sheets is performed in "tongs," i.e., pairs of cast-iron metal plates with a hinge and latch on opposite sides. Baking plate sizes up to 350×730 mm are available. The precisely machined baking plates carry reedings or other engravings. We call the resulting wafers "flat" wafer sheets, with an overall thickness of no more than 2–5 mm (Figure 2, process 3).

But such baking plates can also carry special figures (nuts, sticks, hemispheres, fancy shapes) up to a depth

Table 1 Wafer batter ingredient ranges (weight parts, flour = 100)

	No (low)-sugar wafer	*Higher-sugar wafer*
Wheat flour	100	100
Water	120–160	100–140
Starch	0–12	0–5
Sucrose	0–4	25–75
Oil/fat	0.5–2	1–6
Milk powder	0–2	0–2
Soy lecithin	0.2–1	0.2–1.5
Salt	0–0.6	0–0.6
Sodium bicarbonate	0.1–0.5	0–0.3

Optional minor ingredients: other cereal flours, soy flour, other sugars and syrups, egg-based ingredients; whey powder, yeast, caramel color, cocoa powder, colors, ammonium bicarbonate, enzymes.

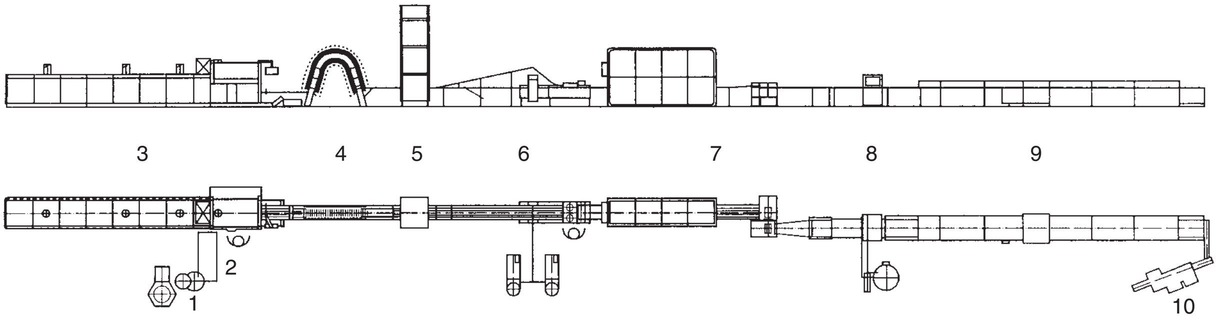

Figure 2 Manufacturing line for creamed and enrobed wafer biscuits from flat wafers. (1) Batter preparation; (2) batter transport and depositing; (3) wafer sheet baking; (4) wafer sheet cooling; (5) conditioning of sheets; (6) creaming and wafer book building; (7) cooling and cutting of books; (8) enrobing; (9) cooling of enrobed pieces; and (10) packaging. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 540, Elsevier Ltd.)

of ~20 mm, thus yielding the so-called "hollow" wafer sheets.

Modern wafer-baking plates often are surface-plated, e.g., with chromium for easier release and reduction of cleaning stops. The plates are edged with metal strips to give a closed baking mold, except for small venting channels for steam release. Wafer-baking ovens frequently have 32–104 pairs of plates, continuously circulating on a chain. They are mostly gas, sometimes electrically heated and operate at mold temperatures between 160°C and 190°C.

The baking process Within a few seconds after batter deposition, the baking molds close and are locked. At first, the batter is distributed mechanically, but then the mold is filled completely by the steam that evolves. A small quantity of batter is extruded as baking waste "bobbles" through the venting channels. As gelatinization of starch starts immediately, the pressurization of the mold by steam occurs at the right moment, resulting in a well-aerated starch foam.

When most of the water has been driven off, the glass temperature of the wafer matrix rises, and the stable structure is formed. The temperature of the wafer increases to 160–190°C, i.e., to the temperature of the baking mold. Then, from Maillard reactions, the typical wafer color and flavor develop.

The overall baking times are between 1.5 and 2.5 min, depending on the wafer thickness and baking temperature.

During the wafer manufacturing process, there is no substantial degradation of starch molecules compared with other bakery products such as extruded cereals. Therefore, wafers have two unique textural properties:

1. Extreme crispness on biting and initial chewing.
2. Good mouth feel during prolonged chewing and swallowing owing to the absence of sticky, glutinous stimuli.

Wafer Release and Cooldown

At one end of the oven, the plates open to release the baked sheets and to spread fresh batter, and then reclose very quickly. The sheets are cooled to room temperature while passing over an arch-type sheet cooler (Figure 2, process 4).

Wafer Conditioning

Next, the wafers optionally pass a conditioning unit, where the moisture content of the sheets is carefully increased so as to achieve some stability in both the texture and size of the wafer (Figure 2, process 5).

Moisture sorption and wafer texture After baking, the residual moisture is 0.8–1.5%. Looking to the sorption isotherm, this corresponds to a water activity of ~0.1 or even lower. As both the water activity of the air in the production area and the water activity of filling creams or coatings are well above that, wafers pick up moisture very easily. In line with this sorption, the dimensions of the sheet increase by 0.2–0.3% for every 1% of additional moisture. This can result in cracking of the coating in enrobed wafer biscuits.

To compensate for the low water activity, humidity conditioning up to ~4.5% wafer moisture is possible. This is recommended, especially if enrobed or chocolate molded wafer products are made, in order to anticipate this first dimension increase and to avoid any cracking of the coating during its shelf life.

Moreover, with increasing water activity, the wafer texture changes from a soft to a harder crispness, accompanied by a higher mechanical stability, which is good both for handling and for the final product texture. Up to 5–6% moisture content, the wafer sheets keep their typical crisp texture, but higher moisture levels will result in most cases in inadequate, tough, or even soft and soggy textures (see Table 2 for details).

Table 2 Water activity, water content, and texture of wafers

Wafer condition	*Wafer texture*	*Water activity, approx.*	*Moisture (%), approx.*
Freshly baked	Very tender, crisp	<0.1	<2
After conditioning	Crisp, harder	0.3	4.5
Limit of crispness	Crisp to tough	0.5/0.55	≥ 6
Wafers, foam-filled	Soft to flexible	0.7	≥ 12
Collapse of structure	Very soft, shrinks	>0.85	>20

Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 541, Elsevier Ltd.

Creaming and Book Building

The sheets then pass the creaming station, where a layer of a sugar- and fat-based cream is applied to one side. The type of cream flavor liked most varies regionally, but chocolate, vanilla, hazelnut, milk, strawberry, and lemon are the most common. Creaming is done at temperatures of 30–40°C either by contact spreading or by depositing a preformed cream film (Figure 2, process 6). For flat wafers, several creamed sheets together with a noncreamed top sheet form a so-called "wafer book."

For hollow wafers, the cream is added to the hollow parts either by spreading or by controlled single depositing. Again, either two hollow wafer sheets or a hollow and a flat sheet are combined to form a "book."

Cooling and Cutting

The wafer books pass a cooling tunnel to set the cream, after which they are wire or saw-cut into small biscuits (Figure 2, process 7).

Enrobing or Molding in Chocolate, Cooling

The cut biscuits may be enrobed with chocolate-type coatings, sometimes after the application of chopped nuts or crispies to the top wafer. Molding in chocolate is another possibility. After a final cooling step, the biscuits are ready for packaging (Figure 2, processes 8 and 9).

Packaging

The biscuits have to be packed tightly to protect against humidity, but also against oxygen and light to prevent oxidative deterioration and to insure a shelf life of 6–9 months. Inadequate packaging-film moisture barriers and bad sealing are the most frequent reasons for later complaints by customers. Laminated or specially coated films are used for the typical wafer product packaging in flow packs, boxes, or bags (Figure 2, process 10).

Manufacturing of Molded Wafer Cones

Another type of "hollow" wafers, cones, cups, and fancy shapes with up to 185 mm in length are produced in cast-iron molds. Holes for four to six items are provided in each of these molds, and 12–72 molds are circulated in one oven. The lower part of the mold is made of two symmetric halves that open to release the baked pieces. After their reclosure, they take up a fresh batter deposit, and finally the "core," the upper part of the mold, closes the mold for a new baking cycle. The baked cones are cooled down and stacked for packaging.

Recipewise, there are two groups of molded cones:

1. No- or low-sugar cones, generally known as "cake cones," whose recipes are similar to those for sheets (see Table 1).
2. The so-called "molded sugar cones" have an intermediate sugar content, usually below 20 parts of sucrose for 100 parts of flour.

Recent Developments in Molded Wafer Cones

Whereas traditionally molded cones have flat tops and regular, symmetric reedings now for a few years, molds for more sophisticated products can be manufactured. We now see cones and cups in the market showing curvilinear tops and artfully designed outsides. Figure 3 shows the first of these, which comes from a Japanese cone manufacturer.

Figure 3 Molded wafer cone: example for new, nonflat top design. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 542, Elsevier Ltd.)

Manufacturing of Rolled Wafer Cones

"Rolled sugar cones" need a concentration of more than 20% of sucrose or other sugars in the finished product. The first three steps of rolled sugar cone manufacturing are rather similar to no- or low-sugar wafer sheet baking with the exception of reduced steam pressure as there are no baking ledges to build up pressure and to extrude "bobbles." The deposit is just to form an oval or circular sheet (see Figure 4):

1. Batter preparation (Figure 4, process 1).
2. Batter transport and depositing (Figure 4, process 2).
3. Wafer sheet baking (Figure 4, process 3). Nowadays, equipment is available to manufacture up to 13 000 cones per h.
4. Wafer take-off, rolling, and cone release (Figure 4, process 4). When, after baking, the mold reopens, the sheet is automatically stripped off the plate and rolled immediately on tapered mandrels to form the finished cone. A series of rolling devices mounted on a round table operates continuously: sheet removal, rolling, release, etc.

Glass Transition and Formability

During the rolling procedure, the wafer temperature is still above the glass transition point. The molten sugar acts as a plasticizer, and so any rolling or deep-forming operation can be performed. Besides the rolled cones, three more types of products are manufactured by the same principle:

1. Wafer "rolls." Wafer sheets of rectangular shape are baked, stripped off the baking plate, and rolled into a sugar wafer "rod" without a center hole (different from wafer "sticks" with a center hole discussed later). The rod is later cut into smaller cylindrical pieces. Typically, these pieces are finally partially enrobed with chocolate-type coatings.
2. "Deep-formed" wafers (cups, shells), where the hot, flat wafer piece is introduced into a forming tool, sometimes with an additional embossing or stamping device, which defines the final shape.
3. Rolled wafer sticks. These are discussed in a separate section below.

Cone Cooling

The fresh cones pass through a cooling section, where ambient or cooled air is applied. Here, sugar recrystallization finishes to give the final strong and brittle texture (Figure 4, process 5).

Cone Sleeving and Stacking

Now, paper sleeves are applied automatically, and these form the packaging material for the typical end product, industrially manufactured icecream cones. Next, is automatic cone stacking and packaging.

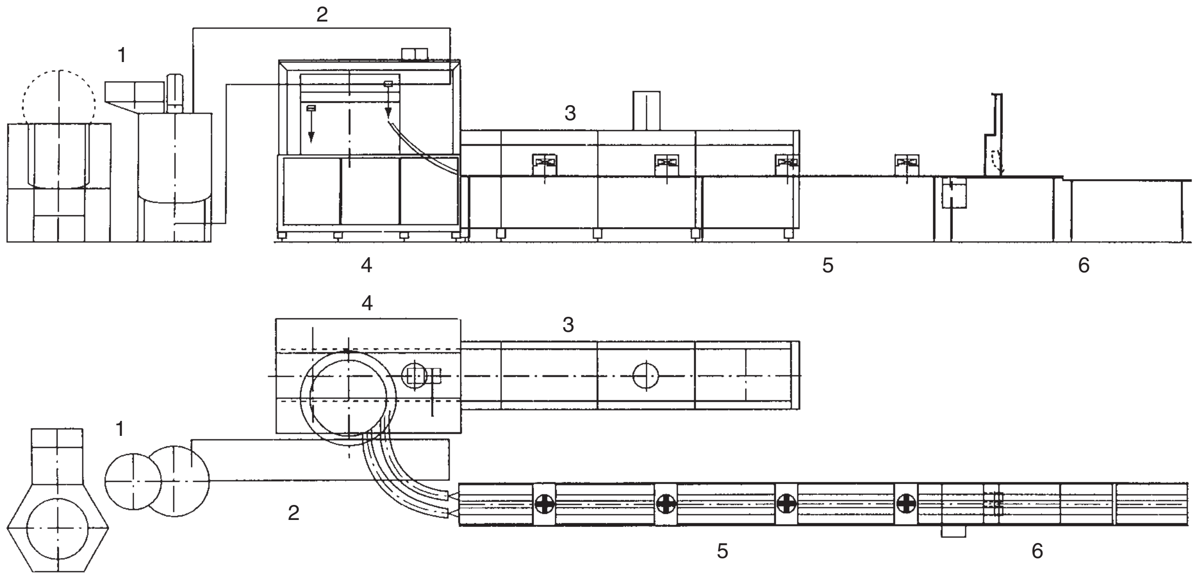

Figure 4 Manufacturing line for rolled sugar cones. (1) Batter preparation; (2) batter transport and depositing; (3) wafer sheet baking; (4) take-off, rolling, and cone release; (5) cooling of cones; and (6) cones sleeving, stacking. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 543, Elsevier Ltd.)

Later in the ice-cream plant, the wafer cones are sprayed inside with chocolate and filled, and finally, the paper cone is closed (Figure 4, process 6).

Manufacturing of Rolled Wafer Sticks

Rolled wafer sticks are hollow tubes with walls consisting of very thin multiple layers, similar in texture to crunchy cereals. These layers do not carry a wafer pattern and are ~0.5 mm in thickness. But from the recipe, the sticks are typical higher-sugar wafers (see Table 1).

In manufacturing, a stripe of batter is applicated to a heated drum and baked into a continuous wafer band. The band is rolled immediately while hot into a continuous still formable tube with an internal diameter of ~6–36 mm. From here, there are several options to create a large family of finished products:

1. The tube is automatically cut into wafer stick pieces and cooled. These are consumed as sweet snacks or with ice cream, for example. Other end uses include intermediate products for confectioners to finish by additional filling or decorating operations.
2. During the rolling operation, the tube is coated inside with compound chocolate or filled with cream, either partially or fully. Then, cutting and cool-down, followed optionally by a coating and/or decorating process, give the finished product.
3. The filled tube is transformed into small pillow-like bits by a combined squeezing–cutting operation.
4. The wafer tube pieces, nonfilled, coated inside, or partially cream-filled immediately after cutting while still hot, pass a pressing station to form oval or even flat pieces. Such flat pieces may form the center of premium-type confectionery items with a chocolate coating, including chopped nuts or cereal crispies, for example.
5. Larger-diameter tubes are pressed flat, and by an embossing and stamping operation, so-called "fan wafers" or other elaborate shapes can be generated.

The diameter and length of the sticks as well as the number of very thin, "glassy" sheets forming the wall of the stick can be adjusted individually. Rolled wafer sticks have a unique brittle wall texture without being too hard in biting and chewing.

Savory Wafer Products

Whereas many end uses of wafers in combination with sweet fillings, coatings, etc. are well known, savory or neutral-tasting wafer products are becoming increasingly popular in some areas. Some examples:

1. Wafers as crispbread, delivering a crunchy but softer texture than traditional hard crisp breads. Besides wheat flour there are several options for other cereal and noncereal flours as raw materials. The products are either neutral in taste to be eaten with sweet or nonsweet toppings or have spices, cheese, and other flavorsome ingredients.
2. Wafers – flat or hollow wafers – with savory fillings, e.g., peanut butter or cheese creams.
3. Wafer sticks, a recent development, made from a nonsweet but still rollable material. These are typically combined with savory cream fillings.

Trends – From the Very Wafer to a More Sophisticated End Product

After discussing the different wafer types and their traditional end uses (for an overview, see Table 3), a sharply increasing number of new confectionery brand products during the last decade are worth mentioning. Here, wafers are only a smaller, but still important, part of the deal. These are small confectionery pieces, mostly in bite-size or sectioned

Table 3 Which product from which wafer type?

End product	*No (low)-sugar wafer*	*Higher-sugar wafer*
Wafer crisp bread	Flat wafer sheet	
Sugar wafer biscuits, creamed	Flat wafer sheet	
Wafer biscuits, creamed and enrobed or molded in chocolate	Flat wafer sheet	
Containers, e.g., for ice cream	Molded cake cone	Molded sugar cone, rolled sugar cone
Confectionery, filled, enrobed, decorated	Hollow wafer *or* hollow + flat wafer	Wafer stick *or* sugar cone, small
Fan wafers		Wafer stick, pressed, embossed
Wafer rolls, partially enrobed		Rolled sheet
Wafer bowls		Deep-formed sheet

bars, often chocolate-covered, where the wafer has three main functions:

1. To add its typical texture and crispness, e.g., to a soft filling cream with a piece of nut and a chocolate cover, thus imparting a multitextured impression.
2. To make the overall product "lighter" in calories and nutritionally, as the wafer part is of an extremely low density and cereal-based.
3. To define the precise structure of the piece, e.g., when holding a soft filling, or, for noncoated pieces, to keep the consumer's hands clean if the filling melts due to warmer conditions.

Looking to some of the current trends, we see increasing interest in combining lower fat fillings such as toffee (caramel). Another trend may be newer fat-free fruit-type fillings with water activities that are so low that the wafers stay crisp. Even some new examples of fillings with a higher moisture, resulting in a "soft" wafer part, can be rolled out.

Developments in Wafer-Manufacturing Equipment

After a long period of just "routine" technical optimizations, recent years have seen a few new technical concepts in wafer-manufacturing equipment:

1. The "stack oven," with the baking plates vertically stacked. Here, the weight of the stack itself eliminates the need for hinges and for closing mechanisms as in the traditional chain oven. Moreover, the floor area needed is greatly reduced. The coming years will show whether that development will find its way into industrial practice.
2. A new "low-emission" heating concept together with a 60% reduction in energy consumption for rolled wafer stick ovens. The key is the replacement of the gas-heated drum by a ring, heated by induction. This results in a new, more consistent and more controllable product quality, and results in the elimination of flue gases and a huge reduction in energy consumption for baking, as the first industrial oven prototypes (Figure 5) showed.

Introduction

The term “cookie” obviously derives from the general verb “cook,” but it has taken the specific meaning of a small flat baked product, generally sweet, made from cereal flour. The equivalent term “biscuit” means twice baked, referring to the low-moisture content of this family of baked products. Low-moisture content and brittleness is also inferred by the term “cracker.” The term “biscuit” is more common in the UK, Australia, and New Zealand, whereas the words “cookie” and “cracker” are more common in the USA, where a biscuit is a chemically leavened bread-type item similar to a “scone” in the UK. In this article, the term “biscuit” is used to include the family of biscuits, cookies, and crackers. The biscuit group of products is distinguished from other baked products by their moisture content of 1–5%, in contrast to finished breads and cakes with 35–40% and 15–30% moisture, respectively.

Characteristics of the Biscuit Family of Products

Wheat flour, sugar, and fat are the basic ingredients, but thereafter the variety is almost endless. Biscuits can be grouped in many ways, based on their texture and hardness, their change in outline during shaping and baking, the extensibility or other characteristics of the dough, or the ways that the doughs are handled prior to biscuit formation. The groups often overlap, so it is important to see how several types of biscuits are related, based on their proportions of fat, sugar, and water, and then to compare their typical characteristics and processing means.

These differences in formulation, processing, and finished product attributes are all a function of the dough consistency or dough rheology. Certain key ingredients, such as flour, fat, and sugar largely determine the dough rheology and thus what type of *forming equipment* can be used to produce the biscuit. Based on these fundamental distinctions, five basic categories can be devised: (1) wire-cut; (2) rotary-molded; (3) bar-shaped; (4) deposited; and (5) cut or stamped. Regardless of the category, there are certain rheological requirements for all biscuits, namely the dough must be adequately cohesive for molding/forming, without excessive stickiness, and the dough must have a short, cuttable texture.

Probably the single greatest influence on (biscuit) dough rheology is the degree of gluten development within a dough. Biscuit doughs generally fall into two broad categories – hard and soft doughs. The viscoelastic properties of hard doughs represent the presence of a protein (gluten) matrix which is developed during mixing and sheeting. Hard dough are stiff, tight doughs that require extensive mixing (work) with a resulting increase in dough temperature. They are similar to bread doughs, except that the sugar and fat contents modify their viscoelastic properties. Hard doughs are usually laminated and sheeted before cutting or stamping. The formed pieces will generally shrink because of the elastic quality of the gluten. During baking, the biscuits may continue to shrink in outline, but become thicker. This type of dough formulation may also be suited for rotary-molded biscuits, due to its firm consistency.

Soft doughs do not have a formed gluten structure, because of their high levels of shortening and sugar, and are generally mealy or sandy in texture. They are usually formed by compressing into dies (rotary-molded) or by extruding and cutting, but some

types can be sheeted, then cut. Dough pieces formed from soft doughs tend to retain their shape until baking, but then they spread or flow, becoming thinner.

Deposit biscuits are the machine-made counterpart of the hand-bagged or "drop" version. Such formulae have been successfully adapted to automated production. Deposit biscuits contain about 25–40% sugar, 65–75% shortening, and 15–25% eggs and possess a spread factor of 79–80 (percentages based on 100 parts flour). (Spread factor is a measure of how much a cookie dough will spread out when it is baked. It is equal to the average width divided by the average height, and then multiplied by 10.) Formulations should be such that excessive spread does not occur and the top design of the biscuit is preserved during baking. Adequate adhesive characteristics of the dough are also needed, so that it will adhere to the band and separate from the main tube of dough when deposited (Figure 1). This type of formula may also apply to wire-cut biscuits, where the dough is forced through a die and cut into disks by a reciprocating wire.

Although there are many similarities between biscuit and cracker formulations, a few key differences should be pointed out. One is the obvious difference in sugar content. Unlike biscuits, crackers are usually made from laminated dough, where thin sheets of dough are alternately layered with fat. Whereas biscuits are chemically leavened, some crackers, i.e., saltines, are yeast-fermented over long time periods to develop the characteristic flavors. The flour used in crackers is commonly stronger than biscuit flour and often dough relaxers, e.g., proteases, are required to increase the extensibility of the cracker dough. Salt further strengthens dough, increasing its resistance to extension. A series of biscuit and cracker formulae is shown in Tables 1 and 2.

Ingredients on the Biscuit Dough

Wheat Flour

Wheat flour is unique among the cereal grain flours in that, when mixed with water, its protein components form an elastic network capable of holding gas and developing a firm spongy structure during baking. The protein substances contributing these properties (gliadin and glutenin), when combined with water and mixed, are known collectively as gluten. The suitability of a flour for biscuit making is generally determined by its gluten. Gluten characteristics are determined by genetics, the wheat's growing conditions, and the milling process.

Wheats are described by millers as hard, medium, or soft, based on the grain's physical characteristics. Hard types tend to have higher protein quantity and quality, possessing a vitreous endosperm, with starch granules tightly packed in a protein matrix. During milling, some starch grains are damaged, resulting in an increased surface area that leads to higher water absorption. The softer wheats have a less compact starch–protein complex which results in less starch damage and lower water absorption. The protein level of soft wheats is usually lower, producing a less-resistant, more extensible dough. These "weaker" flours are traditionally deemed more suitable for biscuit making than the harder flours used for breads.

Flour protein levels needed for biscuit making typically range from 7% to 10% and are often selected by functionality for end use, price, and availability. Flour should contain no more than ~14% moisture. Biscuit flour is typically left unbleached and unchlorinated.

Sweeteners

All biscuit formulas contain sweeteners, which constitute the bulk of dissolved materials in most doughs. Sugars impart sweetness, act as vehicles for other flavors, and create an attractive finish. Sweeteners also increase tenderness, crust color, volume, and moisture retention, while maintaining the proper balance between liquids and solids responsible for product contour/shape. Machining properties and baking characteristics are also closely related to sugar. Sweeteners tenderize the finished product by interfering with gluten hydration and starch gelatinization.

High-fructose corn (maize) syrups are becoming increasingly important, but sucrose from sugar cane or beet is still the major sweetener. Commercial sugars are often categorized as granulated or powdered. Granulated sugars range from coating sugar (extremely fine grain) to coarse. Powdered sugars are made by grinding granulated sugars and screening through fine bolting cloths. Generally, as the size of the sugar crystal increases, the size and symmetry of the biscuit decrease, while the thickness and color increase. Often anticaking agents, e.g., corn starch, are added to insure proper flow of the sugar during raw material handling. Where pumpability may offer a processing benefit, granular sucrose can be combined with water to form "liquid sugar," usually at 67% sugar solids or 67°Brix.

Sucrose may be hydrolyzed (inverted) to glucose (dextrose) and fructose (laevulose) by heating it in the presence of a dilute weak acid or mixing it with invertase enzyme. Sucrose is the standard for sweetness, with an arbitrary rating of 100. Fructose and glucose are rated at 170 and 74, respectively. Their combined sweetness in a completely inverted sugar is 127, sweeter than the starting sucrose. Inverted sugars are used primarily for their hygroscopicity and browning reactions, which contribute moisture retention and color development in the biscuits.

Shortenings and Emulsifiers

Fats are the third major component used in biscuit making, but are considerably more expensive than flour or sugar. Besides being used in the doughs, fats or oils are used as surface sprays, in cream fillings and coatings (such as chocolate), and as release agents. In dough, they tenderize (impart shortness to) the crumb by being dispersed in films and globules during mixing, which interferes with gluten development. Shortening also aids dough aeration during the creaming step. The overall effect improves palatability, extends shelf life, improves flavor and, of course, adds caloric energy.

Animal fats, primarily lard, were originally used by bakers. Compound (part animal and part vegetable source) shortenings and all-vegetable shortenings were then developed. Soybean, cottonseed, palm, coconut, and peanut oils are the primary vegetable sources used in shortening production. Continued advancements in purification and hydrogenation developed vegetable oils that could replace animal fats with equal or better flavors, melting points, consistency, and availability. Because of current health concerns, most bakeries have switched to fats of plant origin. The hydrogenation process used to convert liquid vegetable oils into plastic shortenings suitable for entrapping the air and controlling spread is known to generate some transfatty acids which are sometimes believed to be harmful. This is not normally a major concern for cookie producers or consumers however, with the possible exception of sandwich cookies containing a large amount of a shortening-based filling.

Surfactants (surface-active agents) are given many names by bakers: crumb softeners, emulsifiers, anti-staling agents, or dough conditioners. Examples include lecithin, mono- and diglycerides, diacetyl tartaric acid esters of fatty acids, polysorbate 60 and sodium stearloyl 2-lactylate. Surfactants at low concentrations act to modify the surface behaviors of liquids. They are believed to complex with the protein–starch structure, thereby strengthening the film, and to delay dough setting during baking. The behavior of surfactants is due to their amphoteric (possessing both hydrophilic and hydrophobic molecular regions) properties. Their behavior varies according to the charges on the molecules, their solubility, the hydrophilic–lipophilic balance, and the type of functional groups involved.

Surfactants modify dough consistency and reduce stickiness by reacting with the gluten. The greasiness of biscuits with high fat content is also reduced by surfactants. Crumb softeners also complex with the starch molecules to delay retrogradation and texture staling. The grain pattern and volume of the finished product are often improved, as surfactants increase dough gas-retaining properties.

Antioxidants retard the development of oxidative rancidity during product storage. All fats are subject to oxidative or hydrolytic rancidity, which causes objectionable odors and flavors, but antioxidants delay these reactions from occurring within the biscuits' shelf life. They are usually added to bulk shortenings and are important for preserving low-moisture products, which are expected to remain edible for several months.

Is Water an Ingredient?

Water is often thought of as a processing aid or catalyst, rather than as an ingredient. It is incorporated at the dough stage but driven off during baking. Water functions in several ways, including hydrating flour proteins and starch, dissolving sugars, salts, and various leavening chemicals, aiding in ingredient distribution and helping control dough temperature.

A dough's consistency is directly related to its water content, or absorption. Many factors affect dough absorption. Approximately 46% of flour's total absorption is associated with the starch, 31% with protein, and 23% with the pentosans. Acceptable consistency can be obtained only after sufficient water is present to hydrate the flour. This is regarded as bound water and controls the dough's consistency. As bound water layers are "stacked up," some of the water is held less and less strongly, resulting in water that can escape (evaporation) and/or migrate as free water. Water activity (a_w) is an important way to measure and monitor water's mobility in baked products.

Making Biscuits Lighter

Leavening agents aerate the dough or batter to make it light and porous. The leavening action is responsible for good volume, improved eating quality, and a uniform cell structure. Leavening can be achieved by various methods, including yeast fermentation, the mechanical incorporation of air by mixing and creaming, formation of water vapor during baking, and the creation of carbon dioxide and/or ammonia by chemical leaveners. However, creation of the initial air bubbles during the mixing phase is critical before any of the other leavening agents can take effect.

Small products like biscuits that bake quickly need a fast-acting leavener that will release the gas before the structure sets. The most widely used source of carbon dioxide in chemically leavened systems is the reaction of sodium bicarbonate or baking soda ($NaHCO_3$) with an acid, usually the acidic salt of a weak mineral acid. The leavening acid promotes a controlled and nearly complete evolution of carbon dioxide from sodium bicarbonate in an aqueous solution. Some examples include monocalcium phosphate monohydrate $(CaH_4PO_4)_2 \cdot H_2O$, sodium acid pyrophosphate ($Na_2H_2P_2O_7$), and potassium acid tartrate ($KHC_4H_4O_6$). When these agents combine with water, they react to form controlled amounts of carbon dioxide. Sodium bicarbonate also raises dough pH.

Ammonium bicarbonate (NH_4HCO_3) generates carbon dioxide, ammonia, and steam when heated. It increases spread and gives a larger, more desirable surface "crack" in some types of hard, high-sugar biscuits. However, it can be used only with low-moisture biscuits that are baked sufficiently to drive off all residual ammonia.

Other Ingredients

Milk products, eggs, and salt are added for variety. Milk and eggs are viewed as wholesome ingredients by consumers; however, they are among the most expensive.

Milk and whey are good sources of protein and lactose, which aid in shape retention and browning reactions. They add flavor and nutrients, improve texture, crust color, moisture retention, and control spread. They are usually added in dried form.

Eggs contribute color, structure, nutritional value, and some flavor. They affect texture as a result of their emulsifying, tenderizing, leavening, and binding actions. The form of eggs used can be fortified or

whole components (yolks and whites) in the liquid, frozen, or dried state, or combined with sugar.

Salt performs two principal functions in biscuit doughs. The first is flavor. It accentuates or potentiates the flavor of other ingredients (e.g., the sweetness of sugar is emphasized), and it removes the flatness or lack of flavor in other foods. Moreover, salt has a slight effect on the consistency of hard doughs, because it has a strengthening effect on gluten. Salt also controls fermentation and aids in suppressing undesirable bacteria.

Minor ingredients include malt, proteases, mold inhibitors, spices, and flavorings. Though used in relatively small amounts, these ingredients have quite important effects on the sensory and physical qualities of biscuits.

Malt is prepared from barley by sprouting it, then drying it at controlled temperatures. Diastatic malt provides enzymes that break starch into simple sugars and add flavor and color. If the malt is heated sufficiently to inactivate the (amylase) enzymes, for use as a flavorant, it is called "nondiastatic."

Proteases are important in crackers (low sugar). They are often added to modify the gluten framework. The effect of a protease is to make the dough less elastic, so that shrinkage does not occur during sheeting and cutting. Proteases may occasionally be used in cookie production. A dough containing gluten that is too strong will decrease biscuit spread, so proteases can improve the spread ratio.

Mold inhibitors are not generally used in low-moisture cookies and crackers, but some types which are higher in moisture may benefit from their inclusion. Other food products used in biscuits (i.e., fillings, toppings, and creams) may require an inhibitor. Some examples include sodium diacetate ($Na_2C_2H_3O_2 \cdot \frac{1}{2}H_2O$), calcium propionate ($Ca(CH_3CH_2COO)_2$), and sodium propionate (CH_3CH_2COONa).

Added Flavors

Our choice of food is largely influenced by taste and flavor. Smell, taste, touch, and sight are all influenced by the chemical and physical properties of the food. Sweet bakery foods are often selected for this reason. Therefore, selecting the correct flavor is extremely critical. Selection of the best flavor is most often achieved through experience and trial and error.

Biscuits may be flavored in one or more of three ways: adding the flavoring to the dough before baking; dusting or spraying the flavor on after baking; or by flavoring a nonbaked portion such as cream filling, icing, or jam that is applied after baking.

Spices are aromatic vegetable products (tree bark, seeds, fruits, and roots), and are usually finely ground. They improve quality through smells and tastes. The most commonly used spices are cinnamon, mace, nutmeg, caraway, anise, allspice, poppy seed, coriander, ginger, cloves, and fennel.

Flavorings are alcohol extracts from fruits or beans. Vanilla is the most common because it blends with and enhances other flavors. Flavorings, such as vanilla or almond, can be either natural or synthetic. Because flavorings are volatile, much of them may be lost during baking.

Added Colors

Color additives are used in biscuits and in fillings, icings, and coatings to create a perception of quality and richness.

Changes during Baking

Chemical changes Biscuits are usually baked in a tunnel oven. The dough pieces are placed on either a flexible metal or wire mesh band that travels continuously through the oven's length, which may reach 100 m. Baking is controlled by varying the temperatures in the individual zones within the oven. It is not uncommon for the drier to consist of 5–7 zones. Baking time is regulated by the band speed. Crackers and some biscuits are docked by pressing blunt pins into the dough sheet. Docking dough pieces before baking creates air passages through the crust and seals the top to the bottom, reducing big blisters.

Dough undergoes several changes during baking (Figure 2). Changes in dimension and texture, loss of moisture, and color and flavor development are the most important. Baking is divided into three phases. The first involves dough expansion and the start of moisture loss. Dough expansion and water loss reach maximum rates and colour development starts during the second phase. The third phase

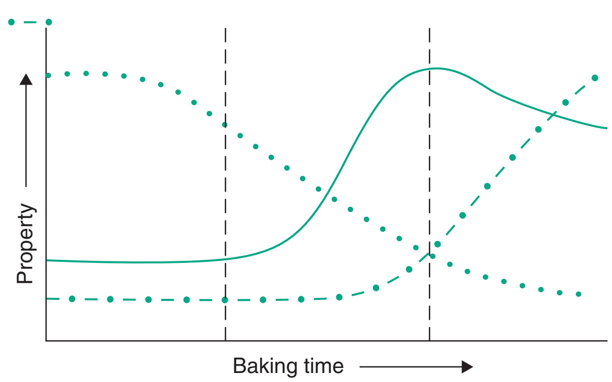

Figure 2 Physical changes in biscuits during baking. Key: • – •, color; ——, thickness; • • •, weight. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 537, Elsevier Ltd.)

concludes baking with a lower rate of moisture loss, thinning of the biscuit, and increasing surface color.

Changes in dimension and texture As dough pieces enter the oven, the biscuit's internal temperature rises, and the sugars and fats melt. The complex matrix contains liquified fat and dissolved sugars. Water evaporation causes the solution to become more concentrated, and the dough temperature continues to increase. Leaveners and steam cause the dough volume to expand. With sufficient heat, limited protein denaturation and starch swelling occur, helping to create some structure. However, the high sugar and fat content inhibit full starch gelatinization.

Doughs rich in fat and sugar, but containing little water, often have unhydrated proteins and ungelatinized starch when baked. With this formulation, a rigid structure cannot be achieved, and is therefore replaced by a soft, sugary matrix. During baking, the dough expands greatly via steam and leavening, but does not set properly, resulting in collapse of the biscuit upon removal from the oven. This expansion–collapse effect is responsible for the characteristic cracked surface of some biscuits.

Changes in moisture Dough moistures average 11–30% before baking and 1–5% after. Moisture can be lost only from the biscuit surface. It migrates from the center to the surface of the biscuit by capillary action and diffusion. The free water is evaporated very readily, but part of the bound water will also be liberated, in association with color development. Moisture content and water activity are critical parameters, as both directly influence storage life.

Color changes One of the most important color reactions is the Maillard reaction. It involves the interaction of reducing sugars with amino groups in the proteins, mainly from lysine, and produces an attractive reddish-brown hue. It is also associated with the dextrinization of starch and the caramelization of sugars. These reactions require very high temperatures, which are reached only at the biscuit surface.

Finishing, Storage, and Staling

In general, freshly baked biscuits are cooled before packaging or secondary processing, e.g., icing or sandwiching with a cream filling. Snack crackers are sprayed with oil and salted/seasoned prior to cooling. The cooling period is usually 1.5–2 times longer than the baking period. During cooling and storage, the biscuit continues to undergo texture changes. Hard dough biscuits are rigid and crisp immediately after baking. Soft dough products are still flexible at the end of baking, but become firm and crisp after cooling, as a result of sugar recrystallization and glass transition temperature.

Changes in Moisture Distribution

The residual moisture is not uniformly distributed as a biscuit leaves the oven. Most of the moisture lies in a lamella near the center, leaving the surface and the outer periphery almost dry.

"Checking" is a change associated with uneven moisture distribution. Dimensional changes within the biscuit after baking cause it to crack. The center shrinks as it loses moisture, but the rim expands as it absorbs moisture. Checking can happen in almost any type of biscuit or cracker, but is most commonly found in semisweet products.

The Diversity of Products

S Zydenbos and V Humphrey-Taylor, New Zealand Institute for Crop & Food Research Limited, Christchurch, New Zealand
C Wrigley, Food Science Australia and Wheat CRC, Sydney, NSW, Australia

Introduction

The diversity of cookies, biscuits, and crackers is evident when one glances along the shelves of a western-style supermarket. This family of products, distinguished by having a low moisture content (below 5%), has a cereal-flour base of at least 60%. The flour is usually from wheat, but it may also be from oats, barley, rye, maize, or rice. The other major ingredients are shortening and sugar. Water is also added, but it is not so significant in quantity as it is for breads and cakes. This article describes the history and usage of cookies, biscuits, and crackers, and the classification of the various types. A range of types is illustrated in Figure 1.

Historical Origins

The name "biscuit" comes from Latin, where "bis coctus" means twice-baked. There is also an Old French word, "bescoil," that has a similar meaning. It is thought that these products have been baked for thousands of years. The original process consisted of baking the biscuits in a hot oven and subsequently drying them in a cool oven. It is very rare to find this double baking technique in modern biscuit production. However, a special type of microwave oven is often connected after a gas-fired oven in factories. Cookie is derived from a Dutch word, "koekje," which means little cake, while the sound of a cracker being eaten probably led to use of that name.

Biscuit, as defined above, is a term used in the UK (and in New Zealand, Australia, and South Africa). The word biscuit is also used for a baked product in the USA. This is a leavened bread-like product that is similar to the UK scone and is not discussed in this article. In the USA, the word cookie describes the same type of products that are called biscuits in the UK. Cracker is a generic term used throughout the world and refers to products with very low sugar and fat contents.

The low moisture content of biscuits, cookies, and crackers means that these products have a long shelf life and a relatively low risk of spoilage by microorganisms. This has led to a history of usage in epic journeys, such as the flight of the Israelites from Egyptian slavery and the sea voyages of the fifteenth-century explorers. British and European traditions usually served biscuits in a semiformal situation with tea or coffee between main meals, especially in the afternoon. Small biscuits were usually made so that a range of appearances and flavors could be eaten without a large intake of food. Modern biscuits, cookies, and crackers are often used as a casual snack food, especially in the USA. Many of these are much larger than traditional biscuits, as they are sometimes eaten to replace meals by consumers who have busy lifestyles.

Figure 1 Biscuits come in a wide range of shapes, sizes, textures, flavors, and colors. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 526, Elsevier Ltd.)

Classification

Geographic location plays an important role in the classification of biscuit and cookie names. In particular, distinct names are used in the UK and USA, while in other parts of the world, the distinction between biscuits or cookies and cakes is not as clear; these products are often classified as small confectionery products. For example, biscuits in France are often classified under the title "petits fours sec." These words literally translate as small oven dry, giving the implication that these are small, dry baked goods. However, petits fours secs may also encompass other products that are outside the biscuit definition given above, such as cake-, meringue-, and pastry-based products. Biscuits that are too large to be put in the mouth at one time, would be called "les petits gâteaux secs," meaning small dry cakes. A similar distinction exists in Germany where biscuits are called "kekse" or "konfekt," but only if they are small.

In the UK, biscuits are classified on their formulation, the two major categories being hard and short doughs. Hard doughs are similar to bread doughs but have a much stiffer consistency. With hard doughs, the three-dimensional gluten network is well developed during the mixing process, so the dough is both elastic and extensible. The formula for hard doughs is very lean, as the content of fat and sugar relative to flour is very low. Crackers are made from hard doughs, as are semisweet, unsweetened, and savory biscuits. Short doughs are more closely related to cake doughs than bread doughs, although they have less water than a standard cake formula. Short doughs are named for the higher content of shortening or fat than hard doughs. They also have a higher sugar content. The increased levels of fat reduce dough extensibility, causing this type of biscuit or cookie to break easily. The flour in short doughs is given very little mixing, so the development of a gluten network is minimized. The consistency of short doughs has been compared with wet sand; they hold together under pressure but crumble easily. Short doughs have a subgroup called soft doughs that have higher levels of fat and sugar, resulting in a dough with an even softer consistency.

Biscuit classification in the USA is based on the method of processing and, in particular, the way the biscuits are shaped. The four main categories are sheeting or cutting (sometimes called cutting machine doughs), rotary molding, wire cutting, and depositing. Sheeting is used for doughs that would be classified as hard doughs in the UK and is always used for making crackers. The dough is passed through a series of rollers until it reaches the required thickness. The biscuit or cracker shapes are then cut out of the dough sheets using a plastic or metal die. It is important that the dough is strong and elastic so that the biscuits and cracker shapes do not deform when excess scrap dough is removed from around the shapes. Rotary molding is used for short doughs, and requires a dough with a relatively stiff consistency that is not too sticky. The dough is compressed into dies mounted on the surface of a roller, and any excess dough is scraped off. The molded dough piece retains its shape as it is pushed out of the die on to the baking sheet or band. Short doughs may also be shaped by wire cutting, which involves extruding the dough through a die and slicing it with a tight wire at appropriate intervals. The tension placed on the dough during extrusion and the thickness of the wire will vary for different types of doughs. Because soft doughs are similar to a batter, having a semifluid consistency and lacking cohesiveness, they are shaped by depositing. The dough is extruded through a nozzle and dropped on to the baking sheet or band. To achieve uniformity in size and shape of the biscuits or cookies, the flow of dough is cut off at regular intervals.

Types of Crackers

Attributes that distinguish crackers are very low levels of fat and sugar. They are often used as a basis for a savory topping, such as cheese or tomato, but the modern snack cracker, with its tasty coatings and flavors, may be eaten without additions. Crackers may be further subdivided into those that are fermented, including soda crackers, saltines, and cream crackers, and those that are chemically leavened like the popular snack cracker.

Soda crackers have been popular in the USA for over 150 years. They are typically 4 mm thick and 50×50 mm square. The shortening content is 8–10%. Saltines are a smaller, more dainty type of soda cracker with an increased amount of shortening. Traditional soda cracker manufacture involves long fermentation using a sponge starter. Soda crackers have a significant amount of sodium bicarbonate added to the dough (1%), which increases the alkalinity and is the reason for the name of the cracker. Once the dough is mature, it is sheeted to about 4 mm and then laminated 6–8 times. The cracker is cut by making lines of perforations and baked as a whole sheet, a process that minimizes the amount of waste dough. A feature of soda crackers is the nine hole docking pattern on each cracker, set out in a 3×3 grid pattern. After baking, the sheet of crackers is split along the perforation lines, usually to make a block of four crackers for packaging. The final product is quite flaky but crisp. The spring between the docking holes on the top of the cracker should be even, and the

bottom surface should be almost flat with numerous small blisters. Because soda crackers are quite dry and bland, they are not usually eaten alone and are often used as an accompaniment to soup.

In the UK, soda crackers are rare, and cream crackers fill a similar market niche. Despite their name, cream crackers contain no cream! They have a slightly higher fat content (12–18%) than soda crackers. Cream crackers are generally a 65×75 mm rectangular shape and are slightly thicker than soda crackers with ~6.5 mm between biscuits stacked in a column. Unlike soda crackers, they are usually produced as individual units. While, traditionally, the long sponge and dough fermentation process was used for manufacturing cream crackers, modern techniques involve a single-stage mixing and fermentation process, which takes from 4 to 16 h. As with soda crackers, cream crackers are sheeted and laminated. A feature of cream crackers is the laminating "dust," consisting of flour, shortening, and salt, that is applied between the layers of dough. This causes the laminations to lift apart during baking, giving an extra flaky structure. The movement of the laminations and subsequent surface blistering are quite irregular, giving the cream cracker its characteristic uneven surface. Blisters are present on both the top and bottom surfaces. Cream crackers have a final moisture content of 3–4%, which is quite high for a cracker, and along with the increased fat content, the cracker is relatively soft, will not crumble and should "melt in the mouth." Without chemical leavening, cream crackers are bland but have a slightly nutty flavor. They are mostly eaten with a savory topping and are often buttered.

Snack or savory crackers have a more recent history than soda and cream crackers. They have two distinguishing characteristics. The first is that the cracker is sprayed with hot oil as it leaves the oven, and the second is that a topping is applied to the crackers to add flavor. Snack crackers usually contain some sugar (4–10%), which also adds flavor and texture. They are usually chemically leavened, but some snack crackers are made from fermented doughs. Because snack crackers do not have the long fermentation to mature the dough, proteolytic enzymes or sulfites are used to relax the doughs so that the crackers do not deform during sheeting and cutting. Snack crackers come in a wide range of shapes and sizes, but are often round and have docking holes to allow an even lift during baking. Only snack crackers produced by fermentation are laminated. Toppings are generally applied before baking, and include herb, cheese, salt, chicken, and smoke flavors. Sometimes, the crackers are decorated with small seeds, such as poppy, sesame, or celery. Snack crackers have a dense texture and are quite soft. The hot oil spray improves the mouth feel and gives an attractive appearance to the finished product.

Cookies and Biscuits Made from Hard Doughs

Sweet and semisweet biscuits made from hard dough are generally more popular in the UK than the USA. While the gluten network is relatively well developed by mixing, the higher amounts of sugar (~20% of flour) and fat (16–20%) than in cracker doughs make the gluten less elastic and more extensible. Chemicals, such as sodium metabisulfite or other chemical derivatives of sulfur dioxide, can also be used to condition and relax the dough to facilitate processing. Unlike cracker doughs, most hard sweet and semisweet biscuit doughs are chemically leavened. After mixing, the dough is sheeted and formed into shapes. The individual biscuits are cut out of the dough sheet, leaving a web of scrap dough to be removed and incorporated back into the main batch of dough. These biscuits are generally docked and marked with a name or pattern before baking. Sometimes, a milk or egg/milk wash is applied to enhance their appearance after baking, and occasionally, a garnish of sugar or other granular material is applied.

Baked biscuits should have a smooth, even surface with a pale color. The texture of the biscuit is open and even, giving a delicate bite, although this is somewhat dependent on the formula – lower levels of sugar result in a harder bite. The ingredients in sweet and semisweet biscuits are quite plain, so the flavor is usually a mild vanilla, caramel, or buttery flavor. The biscuits are generally served without accompanying food and are eaten with tea or coffee. There are some interesting variations of sweet and semisweet biscuits, such as those that are processed after baking to incorporate a cream sandwich or chocolate coating. The garibaldi fruit sandwich biscuits have a layer of currant or small sultana filling between two layers of hard dough.

Cookies and Biscuits Made from Short Doughs

Most of the biscuits and cookies consumed worldwide are made from short doughs, and consequently the range of shapes, sizes, flavors, and ingredients is huge. Formulae are correspondingly variable, but there are some consistent requirements. Flour is usually weak, with less than 9.5% protein. While there are no rules for the proportions of fat and sugar, which can range up to 100% and 200% of flour weight, respectively, the quality of these ingredients is important since they make up such a large proportion of the dough. Short doughs are usually mixed in a two-stage process with

an initial creaming of the fat and sugar, although modern techniques tend to use the "all-in" mixing method. The doughs are cohesive and plastic but lack extensibility and elasticity. The consistency of the dough will vary according to the requirements of the machinery used to form and shape the biscuits.

As described above, the two main processes for forming short dough biscuits and cookies are rotary molding and wire-cutting. Rotary molding originated from the simple wooden molds often used in monastery kitchens to produce biscuits and cookies containing inscriptions. With a rotary mold, dough is continually fed from a hopper and forced into a metal die on a rotating roller. The formed dough shape is pressed out of the mold on to the baking band as the roller rotates. Unlike hard doughs, which tend to shrink during baking, short and soft doughs generally spread because of the high sugar and fat content. This is a particular disadvantage of rotary molding as the inscription can become blurred. Tight control of the formula is necessary to reduce spread. Rotary cookies should be thin and smooth with no surface cracks or irregularities. Because of their regular size and shape, rotary cookies may be used to make cream sandwiches in the same way as hard sweet biscuits.

Wire-cutting is a form of extrusion; the dough passes through a die and is sliced at intervals by a tight wire so that the formed dough shape drops on to the baking band. Doughs intended for wire-cutting are usually softer than rotary molding doughs, and more chunky ingredients, such as chocolate chips, nuts, or raisins, may be incorporated. A variation on the wire-cutting process is a rout press that extrudes dough continuously. The dies on a rout press are designed to produce strips, which are cut into short lengths before baking. Both of these techniques can be adapted to coextrude by having two different doughs or a dough and a filling coming from separate hoppers into a single die that forms a dual layer cookie (e.g., chocolate/vanilla) or a dough tube often filled with a fruit paste of similar consistency.

Cookies and Biscuits Made from Soft Doughs

Soft doughs have a pourable consistency, are typically rich in fat (65–76% of flour weight), and may be based on whipped egg whites (15–25%). Sugar is ~35–40% of the flour weight. Weak flour is used, and mixing is in a two-stage process. The flour and other dry ingredients are added last, and only minimal mixing takes place to prevent the dough from becoming tough. Often, rich, expensive ingredients, such as ground almonds, coconut flour, or cocoa, are used in soft doughs. However, coarse particles are avoided, because they may block the nozzles during depositing. Dough temperatures are important to achieve the correct consistency for forming the specific type of biscuit or cookie required. Temperatures generally range between 10°C and 17°C. The dough flows from the hopper through a nozzle on to the baking band. The nozzles may be of different shapes and sizes to alter the appearance of the cookie, but because the dough flows a little after depositing, these designs may be rather irregular. Some depositor heads can be rotated to make swirls and circular shapes, while two or more depositors may be synchronized to combine doughs of different flavors or colors within the same biscuit or cookie. Soft dough biscuits and cookies have a soft, delicate texture and a "melt-in-the-mouth" feel. However, these properties make them fragile and subject to breakage, and packaging can also be difficult because of the irregular shapes.

Decorating Biscuits and Cookies

The nature of the final product can be further altered by secondary processing after baking. A wide range of processes are used to finish and decorate biscuits, cookies, or crackers, some of which have already been referred to. Two of the most popular are cream sandwiches and chocolate coating or enrobing. In a cream sandwich, the cream usually makes up ~30% of the final biscuit weight and consists of sugar, fat, and flavorings, such as fruit acids, cocoa powder, and skimmed milk powder. The cream is either poured into a stencil positioned over the top of the biscuit base or deposited directly on to the base. Working with chocolate is technically difficult because of the necessity to control the temperature accurately. The properties of chocolate are quite variable and depend on the ingredients that were used to make the chocolate. Various methods of fully enrobing or partially dipping the biscuit or cookie into a chocolate bath are used, depending on product specifications. Icings, made from icing sugar, water, and sometimes fat or a gelling agent such as gelatine, are another popular finishing on biscuits. Jellies, jams, marshmallow, caramel, fruit, seeds, and nuts may also be used to enhance the taste and texture of biscuits, cookies, or crackers.

COIX

Y Huang, China Agricultural University, Beijing, People's Republic of China
H Corke, The University of Hong Kong, Hong Kong, People's Republic of China
J S Li, China Agricultural University, Beijing, People's Republic of China

Introduction

Coix lacryma-jobi L., commonly called Adlay, Job's tears, adley, adley millet, or coix millet, is an annual crop. Botanically, coix belongs to the tribe Maydeae (Tripsaceae) of the family Poaceae, and it is classified as a close relative to maize. This annual grass is native to India, Burma, China, and Malaysia and has been grown extensively in Southeast Asia for several thousand years. The plant is typically ~1 m high with knobbly bamboo-like stems, and the new "tillers" arise from the base of stems. The glossy deep green leaves are up to 5 cm wide with slightly wavy edges. The flowering and fruiting spikelets are insignificant, the grain is pear-shaped, ~5 mm in diameter, and has a hard, shiny dark brown to gray-black hull. The grain is used in soups and beverages, and is popular in Chinese traditional medicine. It is well known to have pharmacological properties. The ancient Chinese medical book "Pen-tsao kang mu" described it as an effective remedy for a number of maladies and particularly beneficial to the digestive system. Coix has been considered as a good potential germplasm resource for maize improvement because it is tolerant to lateritic soils, low pH, has a low variation in photoperiod, less prone to attacks by viruses, and less susceptible to waterlogging.

Botany

Habit

Coix is a light-sensitive and short-day-length plant and prefers wet soils and cool weather. Although it is an annual crop, the plant is perennial in essentially frost-free areas. It is reported to tolerate annual precipitation of 6.1–42.9 dm, annual temperature of 9.6–27.8°C and soil of pH 4.5–8. It can be grown in a variety of environments – from cool-temperate moist to wet through tropical very dry to wet forest life zones, forest margins, and swamps. Although this annual grass is native to Southeast Asia, it is now distributed throughout the tropical, subtropical, and temperate zones Figure 1.

Vegetative Organization

The coix plant is 70–400 cm high. Its stems are erect or straggling with branches and prop-roots from the lower nodes. The internodes of the culms are solid.

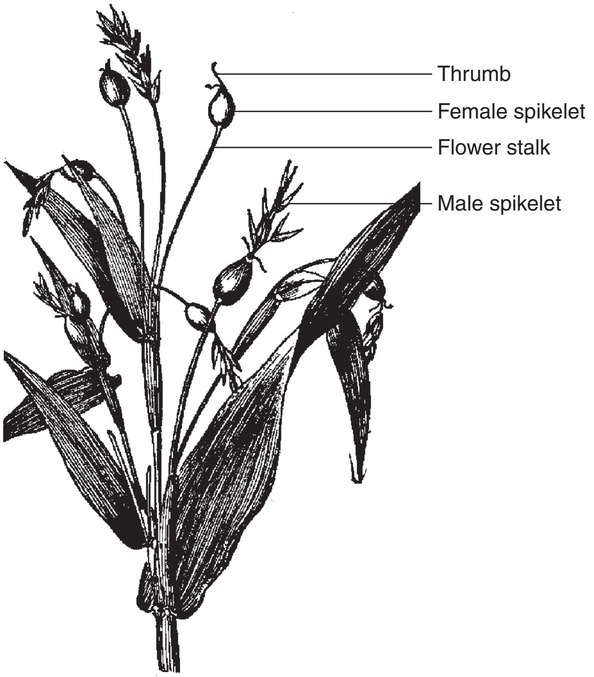

Figure 1 Inflorescence of *Coix*. (Adapted from the images from http://www.desert-tropicals.com/plants/Poaceae/coix_lacryma-jobi.html.)

Leaves are not basally aggregated and nonauriculate, the leaf blades are lanceolate and broad, ~30–70 mm wide, the shape is cordate or not cordate but not sagittate, they are flat and persistent without cross-venation, they are rolled in bud with a ligule present, and there is an unfringed to a fringed membrane.

Reproductive Organization

The coix plant is monoecious with all the fertile spikelets unisexual but without hermaphrodite florets. The spikelets of sexually distinct forms (female-only or male-only) are on the same plant, the glumes of the fertile spikelet are several-nerved and all enclosed finally in a bony beadlike involucre, the involucre containing a minute fertile female flower and two sterile flowers. Pollen-bearing male flowers are produced on a slender stalk that extends out of the bead through a tiny pore. Two feathery stigmata from the fertile female flower also protrude from the pore – ready to receive pollen from the male flowers.

1. Female-sterile spikelets: male spikelets grow in pairs or triads, several per disarticulating raceme. Rachilla of male spikelets is terminated by a male floret. The male spikelets have glumes and proximal incomplete florets or not (the lower floret sterile or male).

Figure 2 The karyotype of *Coix*. (From Zhang Feixiong and Yi Zili (1994) *Natural Science Journal of Changsha Normal University of Water Resources and Electric Power* 9(2): 187–191.)

2. Female-fertile spikelets: Spikelets fall with the glumes. Rachilla terminated by a female-fertile floret. Usually, it is pollinated by the wind.

Seed

The shiny gray to black beads are dispersed and planted like seeds, but they are like little shells containing flowers and grains. The seeds are usually oval-shaped or egg-shaped, with a milky white outer surface and a slightly sweet taste. Fruit medium sized with globular form, 6–12 mm long. Close-up view of flowering coix shows the hollow, beadlike involucres, which have a natural hole in them.

Cytology

The standard karyotype formula is $2n = 20 = 20m$ (*Coix puellarum*). But there are other karyotype formulas outside of the standard types, such as $2n = 20 = 18m + 2sm$ (*C. stenocarpa*); $2n = 20 = 18m + 2sm$ and $2n = 20 = 16m + 4sm$ (*Coix lacryma-jobi* var. *lacryma-jobi*); $2n = 20 = 12m + 2m$ (sat) $+ 6sm$ (*Coix lacryma-jobi* var. *monilifer*); $2\text{n} = 20 = 14m + 6sm$ (+1-2B) (*Coix lacryma-jobi* var. *formosana*), $2n = 20 = 18m$ (2 sats) $+ 2$ sm (*Coix lacryma-jobi* var. *mayuen (Roman) Stapf*). In another research, the chromosome complement of $2n = 10$ and $2n = 20$ was also found in different populations of coix of Indian origin Figure 2.

Biochemistry

Like other members of the grass family, prolamin is the major storage protein in coix seeds. The coix prolamin is known as coixin and represents more than 70% of the endosperm protein. Based on differential solubility, coixins can be separated into two factions: α- and γ-coixins. α-Coixins are constituted by four size classes, while γ-coixins comprise only one molecular weight class. α-Coixins are synthesized at earlier developmental stages than γ-coixins. The deduced amino acid sequence of a full-length cDNA clone encoding a sulfur-rich coix prolamin predicted a polypeptide of 194 residues, which shared 64%

homology with the 17 kDa β-zein. The mature protein contains the familiar composition of prolamins and an unusually high content of the sulfur-containing amino acids methionine (11.6%) and cysteine (5.2%). Hydropathy analysis showed that α-coixin is slightly more hydrophobic than β-zein.

The anticomplementary polysaccharides CA-1 and CA-2 purified from the seed of *Coix lacryma-jobi* L. var. *ma-yuen* both consist of rhamnose, arabinose, xylose, galactose, galacturonic acid, and glucuronic acid but in different ratios. CA-2 contains more mannose and glucose. CA-2 showed more potent anticomplementary activity than CA-1 in low dose. The seeds of *C. lacryma-jobi* L. var. *ma-yuen* Stapf are used as a traditional Chinese medicine reputably possessing antitumor activity, attributed to an acidic fraction. Infrared spectroscopy and gas-liquid chromatography showed that this acidic fraction was composed of four free fatty acids: palmitic, stearic, oleic, and linoleic acids.

A protein inhibitor of locust gut α-amylase which was purified from coix seeds consists of two major isomers, each a dimer of two closely similar or identical subunits of $M_r \sim 26\,400$ Da, and associated by interchain disulfide bonds. These isomers also have closely similar amino acid compositions. The major isomer shows no inhibitory activity against amylases from other sources (human saliva, porcine pancreas, *Bacillus subtilis, Aspergillus oryzae,* and barley malt). This highly specific function may be relevant to protection of the grain from insect feeding and fungal infection.

The gelatinization temperature of waxy coix starches varies between 63.4°C and 76.4°C and water-binding capacity ranges from 103% to 108% respectively. The starch yield from coix grains averages ~45%, the birefringence loss of starch granules begins at 65°C and finishes at 75°C, and breakdown during pasting in a Brabender viscoamylograph is substantial. The properties of waxy coix starch are similar to those of waxy maize starch. Amylose content is the main factor controlling differences in starch properties of coix starches. The amylose contents of normal coix ranged from 15.9% to 25.8%, and those of waxy coix were 0.7–1.1%. Swelling power of waxy coix starches varied between 28.6 and 41.0 g per g, generally higher than waxy maize. Normal coix starches had significantly higher gelatinization peak temperature (71.1–71.4°C) than normal maize (71.9–75.5°C), similar to waxy maize. Rapid visco analyzer (RVA) pasting profiles of normal coix shows some variation but closely matches the normal maize starch profile. Pasting profiles of waxy coix have more variation and lower peak viscosities than waxy maize starch. Waxy coix starches form very weak gels, while the gel hardness of normal coix starches was 11.4–31.1 g.

The complete amino acid sequence of the polypeptide of the major trypsin inhibitor from coix seeds showed 64 amino acids with a high content of cysteine. The sequence exhibits strong homology with a number of Bowman-Birk inhibitors from legume seeds and similar proteins recently isolated from wheat and rice.

The exochitinase praratins, enzymes that catalyze the hydrolysis of colloidal chitin and regenerated chitin to 2-acetylamine-2-deoxyglucose, have an average M_r of 10 000 Da as determined by SDS-PAGE. The pH optima of the two enzymes are 5.0 and they are stable in the range of pH 5–8. The temperature optima are 45°C for (I) and 55°C for (II) (which is a glycoprotein) respectively. They are not stable at temperatures above 55°C.

Whole kernel oil yields and levels of four phytonutrients (free phytosterols, fatty acyl phytosterol esters, ferulate phytosterol esters, and γ-tocopherol) in oils were measured from three coix accessions (*C. lacryma-jobi* L.). Oil yields ranged from 3.03 to 4.83 wt.%, ferulate phytosterol esters in oils ranged from 0.109 to 0.119 wt.%, free phytosterol varied from 0.54 to 0.61 wt.%, phytosterol fatty acyl esters in the oil ranged from 0.79 to 0.98 wt.%, total phytosterols were from 1.43 to 1.69 wt.%, and γ-tocopherol varied between 0.030 and 0.045 wt.%. Whole kernel oil yields of coix are generally higher than *Zea mays* ssp. *mays* and teosinte accessions.

Molecular Biology

The seed storage proteins of coix, sorghum, and maize are coded by homologous genes, which are coordinately expressed in the endosperm in a temporal-specific fashion. Opaque-2 (O-2), a bZIP protein originally isolated from maize, has been described as a transcription activator of α- and β-prolamin genes. The coding region of the coix O-2 gene is interrupted by five introns and codes a polypeptide of 408 amino acids. Comparison of the deduced amino acid sequence with two different sequences of maize O-2 protein showed that the coix O-2 protein is similar to the maize O-2 isolated from a maize inbred line, W22. The coix O-2 protein has the same binding specificity and expression pattern of the maize O-2.

Dihydrodipicolinate synthase (DHPS) is the main enzyme of a specific branch of the aspartate pathway leading to lysine biosynthesis in higher plants. The open reading frame of the DHPS-encoding *DapA* gene from *C. lacryma-jobi* is interrupted by two introns and encodes the 326 amino acid-long coix DHPS protein, which is 95% identical to the maize

DHPS protein. DHPS transcripts are present in coleoptiles, embryos, endosperms, and roots but are almost undetectable in blades of young leaves of both coix and maize. The 5′-flanking region of *DapA* gene contains a TGACTC GCN4-like element located 372 bp upstream from the putative translation start codon. Steady-state levels of DHPS mRNA are slightly reduced in the endosperms and embryos of the maize lysine-rich O-2 mutants when compared with those in normal kernels. Also, the DHPS gene is not under the control of O-2.

Using random amplified polymorphic DNA (RAPD) markers, 21 coix accessions were characterized for genetic variations and relationships. The results indicated considerable variation at the DNA level among the coix germplasm, and the classification by RAPD data reflected the differences in geographic origins and evolution of coix. Recently, a coix genetic linkage map with RFLP and AFLP markers was constructed. The map consisted of 10 linkage groups, consistent with the chromosome numbers observed cytogenetically.

Utilization

Coix may be a weed to some, a source of ornamental beads, a staple sustenance, and a productive fodder grass increasingly viewed as a potential energy source. It has long been consumed both as a nourishing food and as an herbal medicine.

Food

Before maize became popular in South Asia, coix was rather widely cultivated as a cereal in India and still occurs as a minor cereal. Coix was used as food, particularly by peasants in the Far East, very early in agricultural history. In wild varieties, the fruit has a hard, shiny coat. After domestication, this coat became less hard and easier to cook, for example, into porridge. Coix ranks along with wheat and barley in the Near East; beans, maize, squash, and pepper in the Americas; and rice in Asia as one of the earliest domesticated plants. As with other cereals, there are many coix cultivars, including soft-shelled, easily-threshed types with a sweet kernel.

Though the hard seedcoat makes extraction of the flour rather difficult, this is a potentially very useful grain because it has a higher protein to carbohydrate ratio than any other cereal (Table 1). Reported data differ somewhat. According to List and Horhammer, 100 g seed contains 380 calories, 11.2 g H_2O, 15.4 g protein, 6.2 g fat, 65.3 g total carbohydrate, 0.8 g fiber, 1.9 g ash, 25 mg Ca, 435 mg P, 5.0 µg Fe, 0 µg β-carotene equivalent, 0.28 mg thiamine, 0.19 mg riboflavin, 4.3 mg niacin, and 0 mg ascorbic acid. According to *Hager's Handbook*, there is 50–60% starch, 18.7% protein (mainly glutamic acid, leucine, tyrosine, arginine, histidine, and lysine) and 5–10% oil with glycerides of myristic and palmitic acids. The partial amino acid composition of crude protein in coix seeds is shown in Table 2.

Table 1 Composition of coix seed compared with other grains (on 100 g basis)

	Coix	*Rice*	*Wheat*	*Maize*	*Millet*
Energy (cal)	358	349	354	362	353
Protein (%)	14.2	7.8	9.9	8.4	9.7
Fat	3.6	1.3	1.8	4.3	3.5
Starch (%)	67.2	76.6	74.6	70.2	72.8

Coix seeds can be used for baking, mixed with wheat flour, and for making porridge and beer. They are usually pounded, threshed, and winnowed. The pounded flour is sometimes mixed with water, as barley for barley water. The pounded kernel is also made into a sweet dish by frying and coating with sugar. The grains are also utilized in soups, broths, porridge, drinks, and pastries. In India, the Nagas use the grain for brewing a beer called "zhu" or "dzu." A Japanese variety called "Ma-Yuen" is brewed into a tea and an alcoholic beverage, and roasted seeds are made into a coffee-like drink. In some cases, the hulled grain is adapted for parching or boiling like rice, it is also husked and eaten like a peanut. Beers and wines are made from the fermented grain.

Folk Medicine

According to traditional Chinese medicine, coix seeds serve several functions. They stimulate function of the spleen and lung, remove heat, help in the drainage of pus and induce diuresis. Coix seeds have been widely employed as a diuretic, stomachic, analgesic, and antispasmodic agent from ancient times. They are

also used to treat the symptoms of diarrhea and arthritis. The fruits are anodyne, anti-inflammatory, antipyretic, antiseptic, antispasmodic, hypoglycaemic, hypotensive, sedative, and vermifugal. According to Hartwell, the fruits are used in folk remedies for abdominal tumors, esophageal, gastrointestinal, and lung cancers, various tumors, as well as excrescences, warts, and whitlows. This folk reputation is all the more interesting when reading that coixenolide has antitumor activity. It is also a folk remedy for abscess, anodyne, anthelminthic, anthrax, appendicitis, arthritis, beriberi, bronchitis, cancer, catarrh, diabetes, dysentery, dysuria, edema, fever, headache, phthisis, pleurisy, pneumonia, puerperium, rheumatism, small-pox, splenitis, tonic, etc.

Coix seeds are reportedly effective in treating verrucas caused by the human papilloma virus. A tea from the boiled seeds is drunk as part of a treatment to cure warts. It is also used in the treatment of lung abscess, lobar pneumonia, appendicitis, rheumatoid arthritis, beriberi, diarrhea, edema and difficult urination. The action of coix seeds against many kinds of disease can be attributed to various components with pharmacologically different activities. Coix roots can be also used in the treatment of menstrual disorders.

Fodder

The leaves and stems provide a useful fodder for cattle and buffalo. The grass is very suitable for growing in waterlogged areas. Its average yield is 12 t per acre. The grass can also be turned into silage.

Genetic Resources

Coix is reported to tolerate lateritic soils, low pH, slope, viruses, and waterlogging, and to be photoperiod insensitive. It is a potential gene resource for improvement of other cereal crops. It is a perennial plant, which forms several stalks and its pollen can be collected throughout the year when the plant is maintained in a controlled environment. It can be used as the pollen parent for wheat crosses for haploid production without requiring synchronization of flowering dates.

Cultivation

Generally, coix is propagated by seeds. The plant prefers light (sandy), medium (loamy), and heavy (clay) soils. It prefers neutral and basic soils, but can grow in very acidic soil, and it requires moist soil. It is sown at rate of 6–10 kg ha^{-1}. Seed is planted 2.5 cm deep, at a spacing of 60×60 cm. One intercultivation, before the plants tiller and cast shade on the ground may be necessary. The largest plants result when the plant is given partial shade although it will tolerate full sun. It adapts to wet soils so may be used near water. Sufficient rains in early stage of growth and a dry period when grain is setting are necessary for good yields. Plants respond well to liberal applications of organic manure. The grain is usually harvested in the fall when the plant matures, and is dried in the sun. Plants are cut off at base and grain is separated by threshing. Coix yields depend on varieties cultivated in different countries. Usually, unhusked grain yields vary from 2.1 to 3.5 t ha^{-1}.

Leaf blight, caused by *Bipolaris coicis*, is one of the most destructive and major yield-limiting diseases in coix. Plant response to leaf blight is quantitative rather than qualitative, varying greatly among cultivars or lines tested. Yield reductions are primarily associated with decrease in kernel numbers per plant, thousand kernel weight, and percent kernel ripeness. Other diseases common in coix are rusts and smuts. Rusts are caused by *Puccinia* while smuts are caused by *Tilletia* and *Ustilago*. Leaf-gall virus and the nematode *Meloidogyne incognita acrita* also attack this plant.

CONSUMER TRENDS IN CONSUMPTION

E Asp, University of Minnesota, South Anoka, MN, USA

Introduction

Effects of consumer trends on food consumption are a challenge to the entire food system because they are continually changing. A trend is a general change in direction of behavior and attitudes that persists and is strong enough to change consumption patterns. For example, consumer trends influence food behavior and consumer attitudes over time and thus cause changes in food consumption. It is important for all sectors of the food industry to pay attention to consumer trends in order to successfully market their products. This article first presents data that follow changes in the consumption of grain-based foods in the United States for nearly a century, and then describes consumer trends that help explain recent changes in the consumption data.

Data for Consumption of Grain-Based Foods

Food consumption data give quantities for food either available for human consumption or actually eaten by individuals during a designated time period, such as per year, month, week, or day. In the US, the Economic Research Service (ERS) in the United States Department of Agriculture (USDA) compiles high-quality data for food available for consumption, also called food disappearance data. ERS is the only governmental source for this type of data in the US. ERS data are in the public domain and therefore available to everyone. In contrast, food consumption data compiled by private consumer information companies specializing in market research, marketing, and advertising are variable in quality and are proprietary data, i.e., access is controlled by the firms and the data are only available to those who pay for it.

ERS data for food available for consumption are called time series data. These data estimate consumption at the national level expressed as amount per capita (person) per year. The data are published annually for several hundred basic commodities and commodity ingredients. The time series food consumption data presented in this article are for the US. These data show consumption trends over time, which for some commodities date back to 1909. Time series food consumption data are available for most developed countries and for some developing countries.

Food consumption data compiled from information collected from individuals about food actually

eaten in a day, week, or month are called cross-sectional data. Such data in the public domain are available from USDA. Proprietary cross-sectional data are available from private consumer information companies.

Time series data for food available for consumption (disappearance data) use supply and utilization balance sheets to estimate the kinds and amounts of commodities moving through the food distribution channels from production to consumption, Figure 1. The amount of food available for consumption (disappearance) is the difference between available supplies (production, beginning stocks, and imports) and utilization (nonfood and other uses such as exports, end-of-year inventories, seed, feed, and industrial uses). To express consumption on a per capita per year basis, amount of food available for consumption is divided by the resident population in the US plus the armed forces overseas on July 1 of the year studied. Amounts reported are weights of food as sold in retail stores.

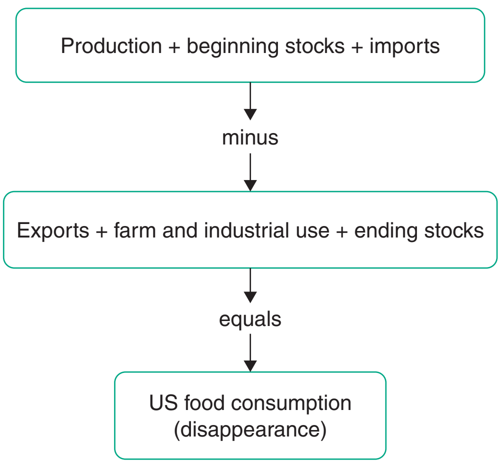

Figure 1 Estimation of food available for consumption (disappearance data) in the US. (Data from USDA/Economic Research Service.)

Time series data have some limitations. They give overall increases or decreases in consumption based on the entire population, but do not give specific food items or amounts of each that are actually consumed by individuals. Changes in consumption in different regions or by different subgroups of the population cannot be determined from time series data. Also, these data overestimate actual consumption because they include waste and spoilage losses throughout the marketing process and in the home. This has been estimated at ~25% of food available for consumption.

The time series data presented in Figure 2 give the total flour and cereal products available for consumption along with data for several specific products – wheat flour, rice, corn products, and oat products – available for consumption in the US from 1909 to 2000. Additional consumption data for specific products show trends in more detail for products with low consumption, rye flour, rice, oat products, and barley products in Figure 3 and corn products in Figures 4 and 5.

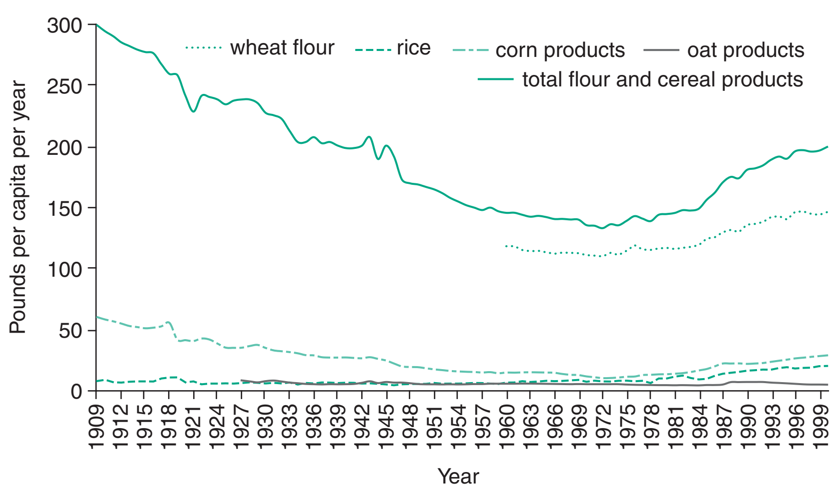

Figure 2 Time series data for flour and cereal products available for consumption in the US. Includes total flour and cereal products (consumption of most items at the processing level, computed from unrounded data, excludes wheat not ground into flour and quantities used in alcoholic beverages and fuel); wheat flour; rice (milled basis); corn products (includes flour and meal, hominy and grits, and cornstarch, excludes corn sweeteners); and oat products (includes rolled oats, ready-to-eat cereals, flour, and bran). (Data from USDA/Economic Research Service.)

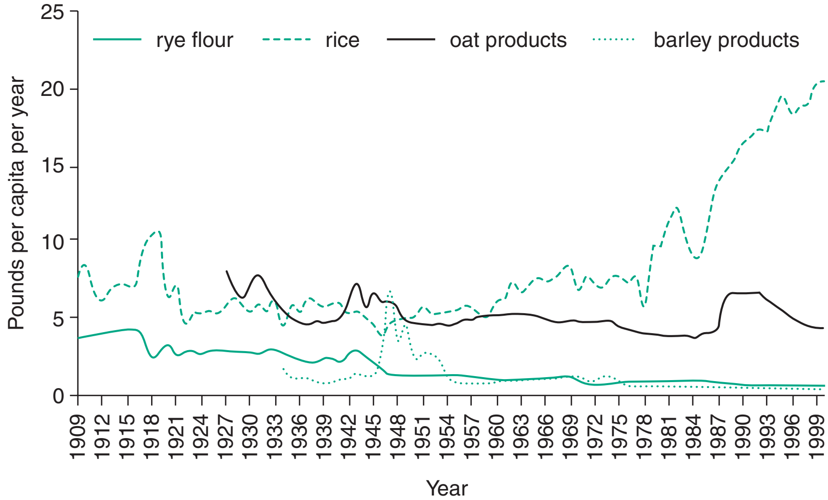

Figure 3 Time series data for different types of flour and cereal products available for consumption in the US showing details of trends at the processing level, excluding quantities used in alcoholic beverages and fuel, for rye flour, rice (milled basis), oat products (includes rolled oats, ready-to-eat oat cereals, flour, and bran), and barley products (includes flour, pearl barley, and malt and malt extract used in food processing). (Data from USDA/Economic Research Service.)

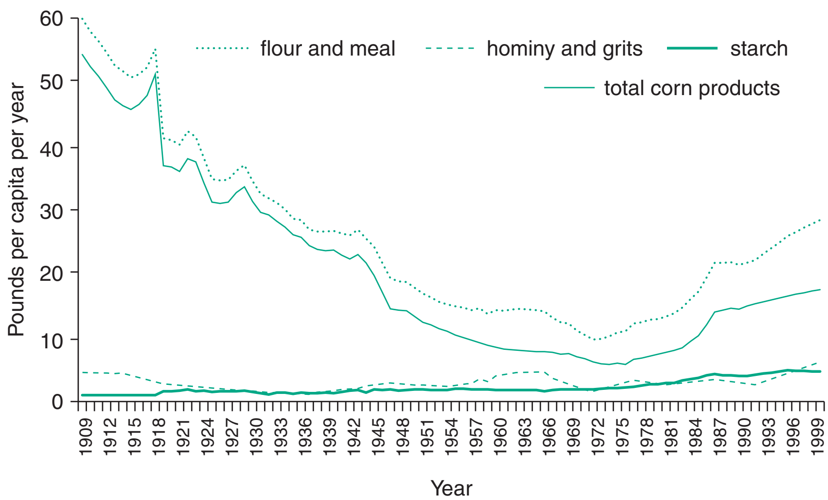

Figure 4 Time series data for corn products available for consumption in the US including total corn products (computed from unrounded data, excluding sweeteners) and for flour and meal, hominy and grits, and starch. (Data from USDA/Economic Research Service.)

The overall trend for total flour and cereal products, Figure 2, shows a continual decrease in per capita consumption from 300 pounds in 1909 to a low of 133 pounds in 1972, followed by increases to 145 pounds in 1980, 181 pounds in 1990, and 200 pounds in 2000. Products included in that total are wheat flour, rice, corn products, and oat products, Figure 2, and rye flour and barley products Figure 3.

Per capita consumption data for the specific products listed above as shown in Figures 2 and 3 indicates an overall trend of decreasing consumption reaching a low for rice in 1946, wheat flour and corn products in 1972, and oat products in 1984, followed by increases since then till 2000 except for rye, and barley products with lowest consumption in 2000. Consumption in 2000 for all products except wheat and rice was lower than in 1909 or in the first year data were available for the products. In 2000, total wheat flour consumption (including 91% wheat flour and 9% durum flour) was higher than that of any other grains at nearly three-fourths of total flour and cereal products consumption, Figure 2.

Per capita consumption of total corn products (except corn sweeteners) was ~14% of total flour and cereal products consumption, Figure 2. Detailed

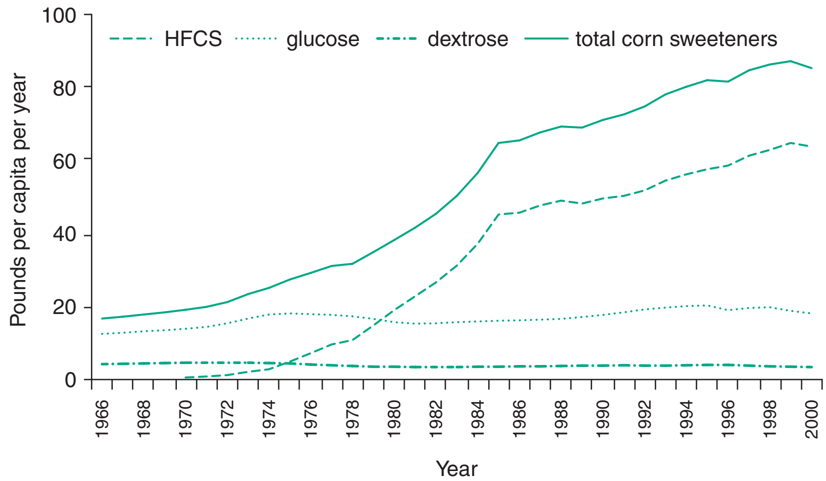

Figure 5 Time series data for corn sweeteners available for consumption in the US, including total corn sweeteners (computed from unrounded data), HCFS (high fructose corn syrup), glucose, and dextrose. (Data from USDA/Economic Research Service.)

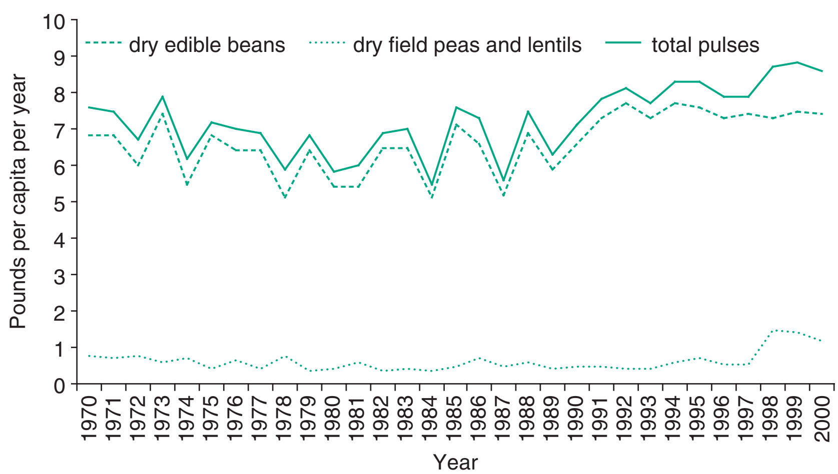

Figure 6 Time series data for pulses available for consumption in the US, including total pulses (computed from unrounded data), dry edible beans (cleaned basis), and dry field peas, and lentils. (Data from USDA/Economic Research Service.)

data for consumption of corn products, Figure 4, show total corn products consumption decreased until 1972, and then increased since then till 2000. Consumption of flour and meal was highest for the corn products and lowest for starch and the hominy and grits. But these consumption data for corn products did not include corn sweetener data, which was first reported in 1966, Figure 5. By 2000, the total for these sweeteners (high fructose corn syrup (HFCS), dextrose, and glucose) was 85.3 pounds per capita, dry weight. Three-fourths of this total was HFCS.

Per capita consumption data for pulses (grain legumes) started in 1970. Total consumption for pulses and dry edible beans followed the same pattern and was higher for pulses than for dry peas and lentils (Figure 6). Dry bean consumption fluctuated at about the same level from 1970 until 1990 when it increased, stabilized, and then slowly decreased until 2000. Dry pea and lentil consumption was stable at a low level until 1998, when it more than doubled, and then decreased slightly until 2000.

Total per capita peanut consumption was relatively stable from 1967, when data started until it decreased to the lowest point in 1980, steadily increased to a high in 1989, and then gradually decreased until 2000, Figure 7. Consumption of peanut butter was the highest of all peanut products and followed the same consumption pattern as total peanuts. Consumption patterns for snack peanuts and candy

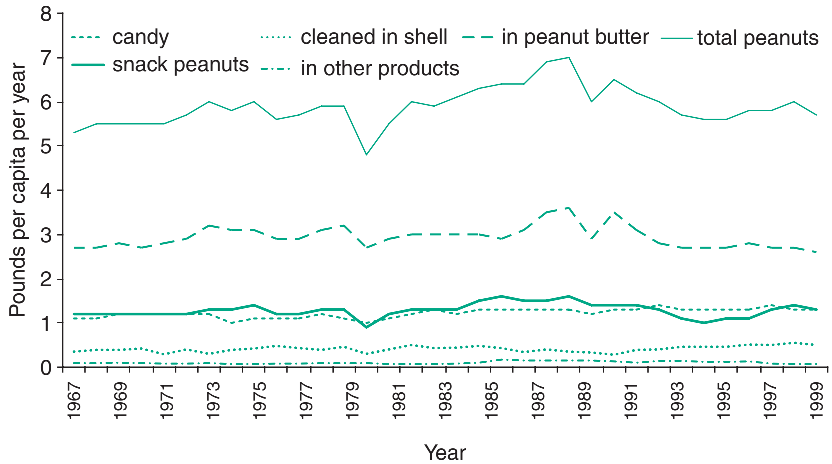

Figure 7 Time series data for peanut products available for consumption in the US including total peanuts (computed from unrounded data), snack peanuts, cleaned in shell (roasting stock, shelled equivalent), in peanut butter (peanut butter made by manufacturers for use in cookies and sandwiches but excludes peanut butter used in candy), in candy, and in other products (includes grated and granulated peanuts and peanut flour). (Data from USDA/Economic Research Service.)

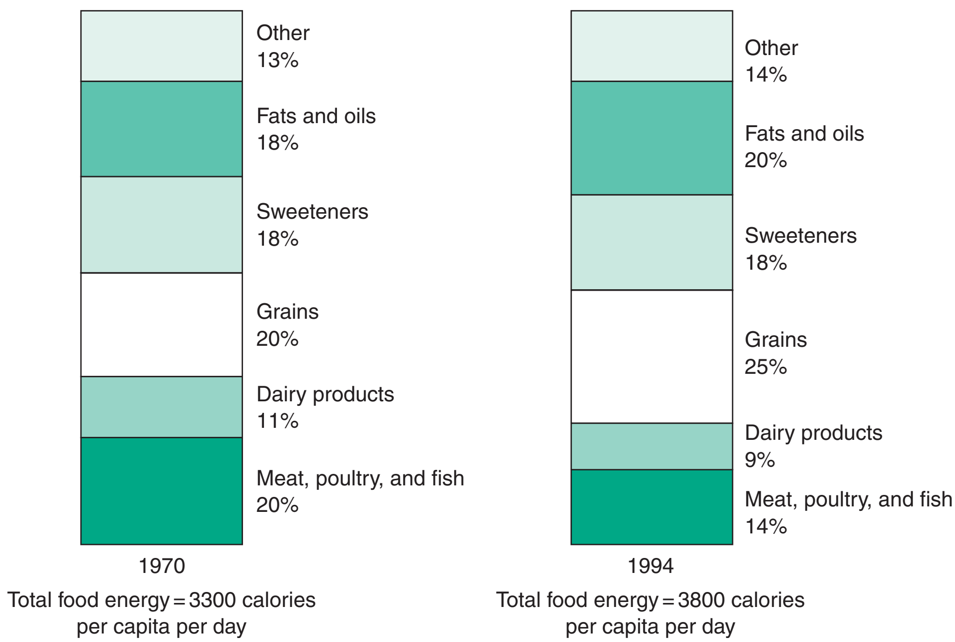

Figure 8 Contribution of grains and meat, poultry and fish groups to calories available for consumption per day in the US food supply in 1970 and 1994. (Data from USDA/Center for Nutrition Policy and Promotion.)

were similar – i.e., lower than for peanut butter. Peanut consumption was lowest for peanuts cleaned in shell and for other products.

Time series consumption data can also be used to calculate the nutrient content in food available for consumption. Nutrient data show that most of the protein intakes in food, in 1909, was from grain-based foods. By 1970, calculations showed that the same number of the calories available for consumption per capita per day were available from the grains group, 20%, and from the meat, poultry, and fish group, 20%, Figure 8. By 1994, the contribution of the grains group to calories available per capita per day had increased to 25% and that for the meat, poultry, and fish group had decreased to 14%, indicating that consumer consumption patterns had changed between 1970 and 1994.

The increases in per capita consumption for most grain-based foods in the US since the 1970s shown by the data described above indicate a continuing

consumer demand for them. Cross-sectional and sales data also show the same trends. This is not surprising considering the wide variety of grain-based foods and ingredients for these foods that is available to consumers and food processors/manufacturers. The food composition table for grain-based foods in the **Appendix**: Grain Composition Tables gives an edited version of these foods and ingredients derived from a large detailed food and nutrient database for grain-based foods and ingredients.

Examples from sales data show the highest sales for the wide variety of fresh breads and other baked products from in-store bakeries, bakery chain restaurants, and for pizza. Complete meal sandwiches, breakfast sandwiches, foreign sandwiches, and mini sandwiches are increasing in popularity. Specialty breads such as artisan breads, stuffed peasant breads, and other ethnic breads, flat breads, and breadsticks are in high demand. Breads with highest sales in restaurants are dinner rolls, bagels, and French/Italian breads. Bread in different forms also is used to package popular portable foods such as wraps, hot pockets, tortillas, pitas, focaccia, and others. Bread also is the main ingredient in the over 45 billion sandwiches consumed each year.

Industry response to consumer demand for quick breakfasts is a wide variety of ready-to-eat and quick-cooking breakfast cereals available. These include whole grain and enriched/fortified rice-based cereals, oat-based items such as rolled oats, oat bran, and quick-cooking flavored oat cereals, and corn products such as cornmeal and hominy grits. Refrigerated and frozen grain-based breakfast items are other convenience products in the marketplace.

Additional examples of popular grain-based foods marketed include many snack foods – crackers, popcorn, pretzels, corn chips, and doughnuts. Fast-food items in greatest demand are various types of buns used in burgers made from beef, poultry (chicken and turkey), fish (tuna, salmon, cod), and other meats. Specialty food service and frozen meal items include bowl meals (noodle bowls), noodle soups, rice salads, sticky rice cakes, lasagna, spaghetti, and other Italian dishes, and many desserts.

Consumer Trends

Consumer characteristics that influence trends in eating behavior and food consumption include demographics, lifestyles, and attitudes toward food. All these characteristics affect the marketing, processing/manufacturing, and agricultural production of grain-based foods. The US consumer trends described here are similar to those in other developed countries.

Demographics

Demographic characteristics that affect consumer trends include age, household size, household income, women in the labor force, education, geographic location, and ethnic background.

Age The increasing age of the population is one of the major consumer trends in the US and in developed and developing countries. By 2050, the median age in the US is projected to be 42, up from 23 in 1900, 33 in 1991, and 37.4 predicted in 2010. The elderly population over age 65 is expected to increase from 35 million in 2000 to 54 million in 2020. By 2030, ~21% of the population will be over 64 years, 12% will be over 74 years, and the ratio of old to young will increase for all races. By 2050, ~50% of the population is projected to be over 50 years.

Age groups, expected to have the largest population increase by 2005, are children and young adults who are the children of the 78 million baby boomers born between 1946 and 1964. After 2005, the number of children is expected to stabilize and then decrease.

Household size Household size in the US decreased from an average of 2.8 persons in 1980 to 2.5 persons in 2000 and is expected to be 2.4 persons in 2020. Smaller households, many of them elderly people in one or two person households, are changing consumer food demands. By 2010, the highest proportion of all households, about one-third, will be "empty nesters" without children under the age of 18. Single person households will increase by 12% and by 2010 and will surpass the number of married couple families with children. No change is expected in number of family households with children by 2010.

Household incomes An overall decrease in household incomes has occurred in the US. The rich are getting richer, the poor are getting poorer, the middle class is decreasing, and a class of unemployable people has developed. Low incomes from the downturn in the US economy and higher than usual unemployment plus an aging retired population with limited incomes will tend to increase economic stress on those segments of the population, while high-income households will be unaffected.

Women in the labor force The number of women in the labor force has more than doubled since the middle of the twentieth century creating two-income families with increased incomes but less time to spend on cooking and housework, more single-parent families headed by working women and more working women in single person households. Their

demands for convenience foods have given product developers opportunities to create products that will increase consumption of grain-based foods.

Amount of education The average educational level of US consumers is increasing overall, but differs within some population groups and in some regions of the country. As education increases, incomes increase. In general, educated affluent consumers have the most information about what to eat to improve their diets.

Geographic location The US population is increasing most rapidly in the south and west with accompanying small increases and some decreases in northern states. People also are moving from farms and small towns to large cities. Only ~2% of the population live on farms and about three-fourths live in metropolitan areas.

Ethnic background Ethnic groups in the US population are increasing. By 2020 the Hispanic, segment is expected to have the greatest increase, and non-Hispanic Whites, Blacks, and Asians are expected to increase at slower rates. Demands for a wide variety of ethnic foods will increase as immigrants continue to come to the US from many different countries. The most popular ethnic cuisines are Italian, Mexican, and Chinese.

Lifestyles

Lifestyle trends of US consumers reveal their diversity. Many lifestyle classification systems have been developed by consumer information firms to describe consumer lifestyles and to help marketers understand how lifestyles affect buyer behavior and food consumption. These systems use a variety of interesting descriptive terms or phrases to identify consumer characteristics for marketers, i.e., who and where customers are, what they want, what they need, what they buy, and how to contact them. Small groups of consumers with similar lifestyles and specific characteristics are called nichés. Using many different marketing techniques to reach nichés of specific consumers identified by lifestyle classification systems is replacing former marketing strategies directed to the mass market of homogeneous consumers that no longer exists. Marketing to nichés helps food retailers choose products to offer in their stores to attract consumers and thus increase profits. Niché marketing of grain-based foods has the potential to increase consumption of these foods.

Attitudes toward Food

Trends in consumer attitudes toward food (shopping, meals, time, cost to prepare) cover many aspects of how consumers feel about food. These include their food habits, food preferences, practices related to food shopping, purchasing and preparation, and overall philosophy about how to provide food for themselves and/or others.

Food habits Food habits indicate how consumers use food. They are based on culture and are passed on from one generation to the next. Food habits specify how and where food is obtained, stored, prepared, served, and consumed.

Food preferences Food preferences express food likes and dislikes. They determine which foods consumers purchase and eat. Food likes and dislikes that influence consumption include familiarity with the quality characteristics of food and acceptance of the aroma (smell), appearance, taste/flavor, and texture.

Food shopping, purchasing, and preparation Although enjoyed by some consumers, many dislike these tasks because they are time-consuming and inconvenient.

Impact of Consumer Trends on Food System Trends

The retail food marketplace, food processing/manufacturing/distribution, and agricultural production sectors are all affected by consumer trends. Grain-based foods are important consumer products that move through each sector of the food system.

Food marketplace trends The retail food marketplace includes food stores and food service establishments. These firms provide food for consumers to buy at reasonable prices. Food stores differ in size, variety of foods offered for sale, number of departments, methods of check out, and customer services. Because of significant decreases in home cooking using individual ingredients (“scratch cooking”) food stores popular with consumers are those that offer a wide variety of convenience foods. All consumers benefit from high-quality convenience foods that are nutritious and require minimal or no preparation and clean up. Those who need these foods the most are the elderly for whom food preparation may be difficult, two-income families with working women, young adults who do not know how to cook, and families in which children have major responsibility for food choices and meal preparation.

Shopping convenience offered by food stores is a response to consumer needs. For example, one-stop shopping in large stores provides busy consumers with everything needed in one shopping trip. And services provided for all, but particularly needed by older shoppers are convenient parking, efficient checkout, grocery packing, and assistance in moving groceries from stores to their transportation home. Large stores are a problem for aging shoppers because it is difficult for them to walk the long distances of the aisles when shopping. To accommodate older consumers, some smaller new stores are now being built.

Food service offers wide choices for food away from home to consumers who now eat almost half of their food away from home. Food service establishments vary from economical fast-food outlets to expensive formal dining, and everything in between. Demand for food away from home increases for small households except those that have low incomes. Most establishments sell takeout food that is usually eaten at home. Trends toward very large servings in commercial food service outlets make consumers feel as if good value is received for the money spent, but another trend has emerged – the tendency to overeat and gain weight.

Food processing/manufacturing trends Food processors add value to basic food commodities by processing them into ingredients used by food manufacturers in the wide variety of grain-based foods in the marketplace. Wheat, for example, is milled into flours used in many grain-based foods.

Food product development adds value to basic ingredients in the form of convenience foods. This gives consumers the option of "not to have to cook," and makes portable foods available that are easy to eat on-the-run. Low calorie, nutrient dense, inexpensive, convenient grain-based foods in small packages that are easy to open are being developed for the aging US population with decreased food and calorie needs and increased nutrient needs. These changes in food and calorie needs of the elderly could decrease consumption of grain-based foods in the future. Special dietary foods and nutraceuticals (foods containing certain beneficial ingredients) are being developed for the increasing number of people of all ages with chronic diseases. However, development of unique and expensive grain-based foods, particularly ethnic foods, which are being developed for affluent consumers can be expected to increase in the future. These foods contain a variety of grains as ingredients and are from the most popular ethnic cuisines, Italian, Mexican, and Chinese, as well as from cuisines increasing in popularity such as non-Chinese Asian, Caribbean, Middle Eastern, and Mediterranean.

Increased consumption of creative, convenient, and nutritious grain-based foods, including popular ethnic foods, can be expected by the increasing number of young adults in the population who are noted for their inability to cook and their need for quick solutions to their food needs. The problem of overweight and obesity in adults and children in the US has increased demand for development of low calorie grain-based foods.

Agricultural trends Agricultural trends are changing as consumers are more demanding, particularly about the quality of their food. Consumers have an impact on what farmers produce and sell. Fewer farms are small independent units with the farmer deciding what to produce, harvest, and sell each year. Specialized contract farming is more prevalent in which the farmer contracts with a large, integrated corporation to produce one product. In the case of grains, farmers contract with a corporation to grow specified grain(s) according to the directions provided. The farmer knows ahead of time what product quality is expected and both the farmer and the corporation will know what will be paid for it. This arrangement may or may not be advantageous to both parties depending on the contract. Only a small proportion of the retail price of manufactured grain-based foods goes to farmers for the grains used in them.

Organically produced food is increasingly being demanded by consumers. This has lead to expanded marketing opportunities for organic farmers and the establishment of governmental standards for the production and labeling of organically produced foods. Organic production standards include methods for handling crops, livestock, and processed agricultural products. In 2002, the USDA approved national labeling standards for organically produced agricultural products that give consumers assurance of consistent organic product labeling throughout the country. In recent years, organic farmers have increased their use of direct-to-consumer marketing, mostly in farmers markets. Supermarkets also have increased offerings of clearly labeled organic foods. Organic grain and oilseed farmers produce wheat, corn, soybeans, oats, barley, sorghum, rice, spelt, millet, buckwheat, rye, dry peas, lentils dry beans, flax, and sunflowers mostly for food processors.

Globalization Trends

Grain-based foods are staples of the food supply in every country. Grain imports and exports are very important not only to help distribute grain supplies globally, but also to contribute to the agricultural economy. Seasonal effects on the market occur

because crops are harvested at opposite parts of the year in the two hemispheres. Time series data provide the information from which appropriate quantities of staple grains can be either exported or imported by different countries to balance supplies and also to meet the nutritional needs of the population.

Summary

Consumption data for grains and grain-based foods change over years because changes occur in consumer trends. Time series data from ERS for grain-based foods available for consumption from 1909 to 2000 in the US show that per capita consumption for some grain products increased and some decreased over that time period. A gradual increase in rice consumption occurred since 1909 and in wheat flour consumption since 1960 when data were first available. Wheat flour had the highest consumption of all grain products. Data for the other grains since ~1970 show a continuing increase in consumption until 2000 for all products except rye flour and barley products. Sales data for grain-based foods in recent years show similar trends.

Consumer trends help explain consumption trends for grain-based foods. Major consumer trends include demographics (age, household size, household income, women in the labor force, amount of education, geographic location, ethnic background), diverse lifestyles, and consumer attitudes toward (food habits and food preferences). Consumer trends that affect movement of grain-based foods through the food system include food marketplace trends, food processing/manufacturing trends, and agricultural trends. Major trends in the food system include niche-marketing, development of grocery stores to improve food shopping convenience, increased demand for and development of convenience foods, and the growing demand for food away from home. Globally, grain-based foods are staple foods in every country. Consumption trends provide information on grain supplies available to export or import among countries to balance supplies and provide for nutritional needs worldwide.

CONTAMINANTS OF GRAIN

J McLean, GrainCorp, Narrabri, NSW, Australia
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

Ideally, grain should be harvested in sound and clean condition, without any form of defect or contamination. Realistically, however, there is always the likelihood that the grain will be harvested together with nongrain material and with weed or crop seeds, all of which detract from the value of the harvested crop. The loss in value relates partly to the fact that the resulting consignment of grain does not contain 100% of the type of grain ordered, but worse than that, it is likely that the nongrain materials will cause problems with the processing of the grain, or that they may even render the grain unfit for the designated purpose or for any use.

Historic Perspective

Primitive man, as the hunter-gatherer, had to accept whatever material grew with the seeds that were collected laboriously from wherever they could be found. As a result, the presence of contaminants must have been considerable. Presumably, this unsatisfactory situation was one of various stimuli for early man to progress to cultivation and seed sowing, thereby to improve the purity and quality of grain foods. Nevertheless, throughout the Middle Ages, the presence of contaminating material was generally extensive, because of poor agricultural practice and also due to the lack of purity of the seed for sowing.

Significant improvements in grain quality have been forced as a result of the progressive change from subsistence agriculture (the farmer's family consuming what they produce) to trading in grain (provision of the grain produced for sale, in competition with others). The past century has seen the extension of trading from the local situation to major international marketing and transport on a large scale (*see* **Cereals: Overview**). As a result, standard specifications have been established for the various grades of grain, based on quality, offered for trade within a country and internationally. Examples of these specifications are provided in Tables 1–3.

An important part of these specifications is the levels of contaminating materials, the higher-value grades being those with the least foreign material. Examples of these specifications can be examined on the websites of the export corporations of major grain-trading countries. The first two examples in Table 1 contrast a premium Australian wheat grade (prime hard) with a lower grade (general purpose). The former has tighter specifications for all aspects of physical quality, compared to the lower-value grade, including the requirement for less material in the category of contaminants.

Types of Contaminants

Nongrain material goes under various names, depending on local terminology and on the species of grain involved. Common terms include "extraneous matter," "unmillable material," "dockage," "besatz," and "screenings." This last term alludes to the general practice of screening the grain through sieves of suitable size to separate material that is larger or smaller than the normal size range of the grain involved. The act of sieving to determine screenings is illustrated in Figure 1. The amount of these screenings is a significant measure of grain quality, as it indicates the proportion of the grain consignment that is not the grain purchased. In addition, the nature of the nongrain material is very important, depending on which of the following categories are involved.

Plant Material from the Grain Crop

Most obviously, nongrain contaminants are derived from the plants that produced the harvested grain. This includes parts of the husks, leaves, and stalks. For the cereal grains, it is not uncommon for the tips of the heads to be included with the harvested grain. This occurs for varieties that may not fragment as readily as others during harvesting. This is due to the dilemma facing the breeder in selecting the best genotypes for the harvest operation. On the one hand, it is desirable to have a variety that "shatters" readily, so that the grain is released from the head on harvesting. However, this characteristic is likely to carry the significant disadvantage that some of the grain will be prematurely shed onto the ground before or during harvest, thus reducing the yield of available grain.

In addition, if the settings of the grain-harvesting equipment are not correct, there will be excessive inclusion of plant parts with the grain or damage to the grain. The resulting presence of shattered or half grains is undesirable, because they are more susceptible to insect attack and to further damage during grain handling and transport. The risks of such undesirable consequences during harvest and transport are greater in very dry, hot conditions.

Hot, dry conditions are also conducive to the production of grain dust – fine particles, comminuted from the plant material and even from the grain itself. Ongoing handling and transport of dry grain is likely to produce more grain dust, as grains rub against each other when it is "turned" or moved from storage facilities to transport containers (trucks or rail cars). Figure 2 shows that grain dust is largely composed of fragments broken from the surfaces of grains. In the wheat dust (Figure 2a), there are short hairs from the brush end of the grain, and also fragments of the bran layers, as well as starch from the endosperm of grains that have been completely broken. The dust from barley (Figure 2b) shows long spear-like structures (broken pieces of rachilla hairs) as well as fragments of awns, lemmas, and paleas (*see* **Grain and Plants, Morphology**). It is a controversial

matter in international trade as to whether the accumulated dust should be removed before shipping grain, or whether it is a legitimate part of a grain cargo. In any case, the dust generated during grain handling is a significant health problem, causing irritation to the bronchial tract as well as to the skin. Dust also creates safety concerns due to its explosive potential; therefore dust reduction is a high priority at grain storage centers.

Figure 1 Sieving of a grain sample to remove screenings (nongrain material).

Defective Grains

Defective grains may be regarded as undesirable contaminants, even though of the same grain species. Such defects include:

- Immature cereal grains – these may have come from side tillers that formed at a late stage compared to the main tillers of the plant. Alternatively, it may indicate that varieties of different maturity have been sown as a mixture. These grains are likely to be green in color and "sappy" in texture.
- Sprouted grains (Figure 3) – these are grains that have become wet, and have thus started the germination process (*see* **Cereals**: Grain Defects).
- Sun-cracked rice grains – these are grains that will probably fall to pieces during rice milling (the removal of the outer bran layers), thereby reducing the yield of whole rice grains.

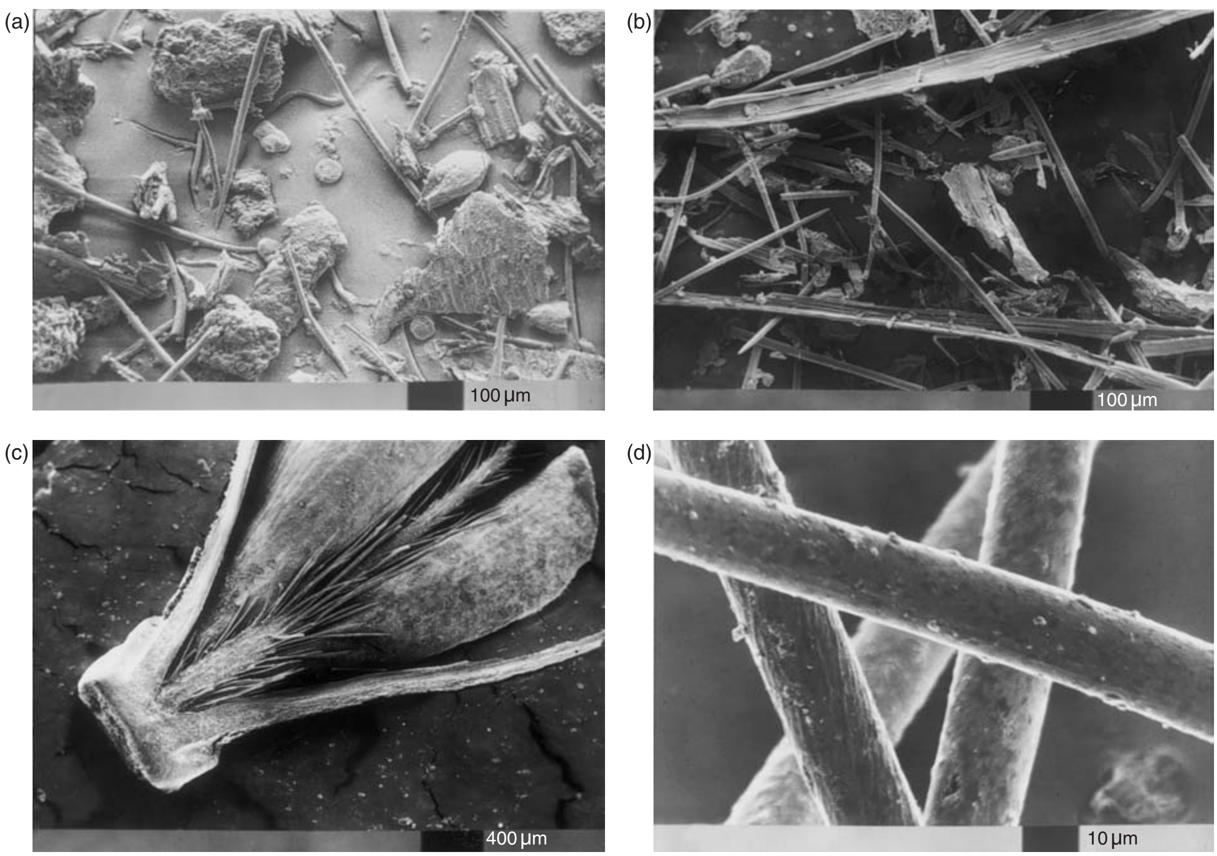

Figure 2 Scanning electron micrographs of grain dust from (a) wheat and (b) barley. The photo of half a barley grain (c) shows where the rachilla hairs have been broken from the base of the rachilla. The rachilla hairs are also shown at greater magnification (d). In each photo, the black bar at the bottom, near the right side is: (a) 100 µm, (b) 100 µm, (c) 400 µm, and (d) 10 µm.

- Vitreous content, pinched grains, black point, frosted/distorted are very important but controversial defects. Ear cockle (seed-gall nematode), a disease caused by *Anguina tritici*, must be detected as it is an object of exclusion due to quarantine in certain countries, especially in Iran.

Infected Grains

Various forms of infection with microorganisms cause grains to become dangerous contaminants (*see* **Cereals**: Grain Diseases). For example, grain that is harvested with a high moisture content (>16% moisture) may be infected with molds, commonly called field fungi, such as *Fusarium* and *Alternaria* causing, in turn, the production of mycotoxins. Because these toxins are active at very low concentrations, e.g., a few ppb, their detection is difficult. They are not necessarily present in visually spoiled grain (e.g., moldy), so there is the need for ready means of testing. Immuno-assay kits are a means of doing so quickly and in "field" situations. If not detected, mycotoxin-affected grain may cause severe illness or death to humans or animals. Grain affected by field fungi may be dark brown, gray, or various shades of black discoloration or pink, especially when affected by *Fusarium* spp.

Ergot infection is another serious contaminant, mainly present in rye, rye grass, canola, and to a lesser extent, wheat. In this case, the ergot fungus (*Claviceps purpurea*) infects the flowers of the cereal grain, producing an ergot body in place of the grain (Figure 4). The ergot bodies often thresh intact, easily recognizable in grain samples as black bodies (sclerotia) larger and longer than the normal grain length. The extent of ergot contamination is generally specified as a percentage by weight, but the length of ergot bodies placed end-to-end is a simple measure used in practical situations. Harvested grain of any species may contain ergots from other species, especially from rye grass (*Lolium perenne*). Any of these sources of ergot produce toxic alkaloids, which may cause injury in cattle when present at a level as low as 0.05%. On the other hand, some poultry species appear to be much more tolerant to ergot poisoning (*see* **Cereals**: Grain Diseases).

Another serious infection of cereal grains is bunt, also known as ball smut or stinking smut, caused by *Tilletia caries* or *T. foetida*. This defect also involves the replacement of the endosperm of the grain by bunt spores, which have a pungent unpleasant odor. As a result of this form of contamination, sound grain may be tainted by admixture with bunt-affected grain (Figure 5). If these grains are broken, black bunt spores spread through the grain as a further source of contamination. In the case of wheat, the bunt spores catch in the brush hairs of sound grains (Figure 6).

In grain storage, excessive moisture can lead to moisture migration and "bin burn" of the grain (causing heat damage and moldy appearance) resulting

Figure 3 Sprouted heads of wheat. The heads have become wet when harvest ripe. The one at left is a sprout-susceptible variety and the grains have started to sprout inside the head.

from the development of field fungi, which may produce dangerous toxins and offensive odors.

Other Crop Seeds

Commonly found contaminants are the seeds of other crop plants. These are likely to be species whose plants are of similar size and maturity to the target seed. It is thus difficult to avoid harvesting them together with the intended crop. Such foreign seeds are likely to be other agricultural species (e.g., barley or rye in a wheat crop) that has been present in the seed sown, or that have been carried over from a previous crop at this growth site. Such contaminants may not be critical unless they interfere with the subsequent processing of the grain, such as milling into flour. A further consideration is how readily they can be removed, if their removal is essential, because this exercise will add to processing costs. Oilseeds, for example, pose the threat of disrupting wheat-milling equipment with the build-up of oil residues, although contaminants such as canola are relatively easy to separate from wheat before milling.

For a wheat consignment, there may be no need to remove minor contamination with other cereal grains, such as barley and oats (up to ~5%). Canadian research has shown that flour yield decreased by ~0.4% for each addition of 1% of barley added to a wheat sample. Milling stocks fed well during flour milling, despite the barley contamination. Likewise, the effects of contamination of wheat with cultivated oats (or even wild oats) were similar to that of barley, except that at 5% addition, oats caused difficulty with the milling process.

Weed Seeds

Weed seeds present problems of greater severity than crop seeds (Table 4). Some weed seeds are the same size as grain kernels, which make it virtually impossible for them to be sieved out of a parcel of grain (e.g., *Phalaris*). For a start, agricultural authorities must restrict the seeds of noxious weeds, due to the threat that they pose to cropping and grazing. However, in small amounts, their presence may not be serious to agriculture because they are likely to be destroyed by processing, such as flour milling. If wheat contains seeds with a dark seedcoat, they are likely to cause dark specks in flour, which can decrease the visual appeal of the end product for the market. On the other hand, some weed seeds cause serious problems because some are toxic to humans and animals. In this category are species such as castor oil seed (*Ricinus communis*), Mexican poppy (*Argemone* species), and thornapple (*Datura* species). Ricin, the toxic principle in the castor oil seed, is reported to be one of the most toxic plant substances known.

Tainting seeds, whose scent may taint a whole consignment of grain, must be avoided, and they are generally specified as "nil tolerance," i.e., none of this type is allowed. In Australia, for example, seeds called "Hexham scent" (*Melilotus indicus*) impart their scent to the grain with which they may be mixed, with the risk of a large consignment of grain being tainted by the presence of a relatively small

Table 4 Groupings of contaminating seeds (a few examples only) used by the Australian wheat industry to indicate their severity as contaminants

contribution of grain with this contamination; similar problems may be produced by the presence of eucalyptus leaves. Animals will probably reject feed grain if it is tainted. Alternatively, if they do consume it, the taint may be passed through to the animal by-products, such as milk.

There is naturally great variation in the range of weed-seed species that are relevant to specific regions and grain species. Regional and national booklets are published for many grain-growing regions, illustrating a relevant range of weed and crops seeds. Examples of weed seeds that must be identified and restricted are shown in Figure 7.

Insects

Insects that attack grains are a serious case of contamination (Figure 8). Accordingly, there is a "nil tolerance" for live insects in many regions (Tables 1–3). This specification may be relaxed to a small extent in the cases of dead insects and for species of insects that do not attack grains, (on a case-by-case basis only) such as field insects. Infestation with grain-attacking insects (previously or currently present) may be indicated by the presence of grains that have been partly eaten by insects (Figure 9).

There are two main types of grain insects. Primary insects are more destructive as they can attack sound grain, while secondary insects can only attack grain that has been damaged. Insects can deplete the energy value of the grain, greatly reducing its value even for stock feed. Insect infestations are often associated with bad odors. Due to the serious threat that some insects can impose, there is a strict nil tolerance on specific species. For example, the Khapra beetle, *Trogoderma granarium*, is the world's most serious insect pest. This insect does not occur in some countries (e.g., Australia). However, the warehouse beetle, *T. variable*, is often mistaken for the Khapra beetle and this can jeopardize not only the acceptance of a parcel of grain but the whole country's reputation.

Animals and Animal Products

Further contaminants include snails, rodents, urine, feces, rodent hairs, birds, bird feathers, and snakes. Snails rarely live more than 2 weeks in storage, so that they are unlikely to reproduce during storage. Most animals contaminate grain through the grain-storage system (with the exception of snails) due to their reproduction and spread throughout the grain store. Rodents and birds are attracted to the grain as a food source and they will often nest there. As a result, there can be the added contamination from the accumulation of their urine, feces, rodent hairs, feathers, eggs, and decaying carcasses. For example, a single rat can produce 12 000 droppings, 2.9 l of urine, and 0.9 million shed-hairs in 6 months. Rodents thus become an important issue, especially when there is a plague. Animals and birds are also potential vectors for diseases. Snakes and some bird species will be present around storage sites, preying on rodents and other birds. All of these animals can become included in a consignment of grain accidentally if present on one of the transport belts or elsewhere on the grain-transport path when it is turned on.

Agricultural Chemicals

Pickling compounds (fungicides) applied to seed grain render the grain unfit for consumption (human or animal). Pickling colors range from bright pink or green through to a slight pink or green coloration. There is a strict nil tolerance for pickled grain as a small amount can render a whole stack unusable. Parcels are regularly checked for pesticide residue levels (obtained through the application of herbicides and/or insecticides). There are tolerances by national regulatory bodies, known as maximum residue limits (MRL). Grain with levels above these limits cannot be used or sold legally.

Grain that is fed to cattle and chickens can transfer the chemicals, thus posing a threat to their markets, with the likelihood that the resulting meat will be prohibited from human consumption. Examples include endosulfan in cottonseed hulls and wheat resulting from spray drift. It is necessary to observe and follow chemical instructions for correct application rates and withholding periods to ensure that MRL levels are not exceeded and to reduce the chance of insect resistance building up.

Heavy metals (mercury, cadmium, and lead) are contaminants that must be tested for routinely as a precautionary measure, especially in industrialized countries.

Inanimate Materials

Sticks, stones, and other inanimate materials cause problems in both analysis and processing, as they can damage grinders and technical equipment. The severity of the material depends on their size. If the material is a similar size to the grain, it cannot be sieved out easily and this can become a serious issue. Such materials can be picked up during the

harvesting process or introduced through the storage and handling processes if equipment is not carefully calibrated and cleaned prior to use.

Tainting Contaminants

In addition to the contamination of grain with tainting materials as a result of harvest, tainting of a grain consignment can occur during storage and transport if a taint or odor is acquired from materials with the grain. One such source can be the packaging material used, in the case of grain that is stored and transported in bags, for example, hessian bags.

GM Grain

With the introduction of genetically modified (GM) grain (initially involving maize, canola, and cotton), and in response to various international market demands, the presence of GM grain within conventional grain delivered can lead to rejection of that grain. Methods are being put into place that will permit

Figure 10 Sampling grain from a truck using a spear sampler.

the detection of such contamination thereby guaranteeing the required grain quality required by specific markets.

Analysis of Contaminating Materials

Given the wide range of contaminants that may be harvested with grain, plus the variations in allowable levels, it is important that there should be rapid means of identifying them. This requirement applies especially to identifying the species of contaminating seeds, since the range of species varies considerably from one region to another. Accordingly, manuals illustrating the range of contaminants are provided for staff training, to inform growers and for use when grain is delivered.

Sampling

However, an essential prerequisite of valid analysis is the initial step of taking a representative subsample of the load being analyzed. Sampling procedures are generally specified together with the manuals illustrating the contaminants. Procedures are also published by grain-trading authorities. The website of the US Department of Agriculture (www.usda.gov/gipsa/pubs/farm-proc/practical_proc.htm) specifies standard sampling procedures for various grain-production situations. Standard procedures for sampling are provided in the Methods of the American Association of Cereal Chemists (AACC) and the International Association for Cereal Science and Technology (ICC) (*see* **Appendix**: Test Methods for Grain and Grain-Based Products).

A critical stage of grain sampling is taking a representative set of samples from a truck when grain is first delivered from harvest to the elevator (Figure 10). In this case, sampling is done so that a whole truck's contents can be observed from above. Routinely, the grain in the truck is sampled by pushing a sampling spear into the grain at several points. This form of sampler is designed to take grain from several vertically separated points throughout the depth of grain. Alternatively, vacuum probes are used to spear the truck in a straight vertical line right down through to the bottom of the load. If the grain is delivered by road, train, or other vehicle with multiple compartments, each bin is sampled three times.

Sieving

An example of the use of mechanical sieving is provided by the routine practice of GrainCorp in eastern Australia using the Agtator (Figure 11). Forty shakes are automatically performed to and fro, as specified by Australian receival standards. The use of a mechanical sieve such as this ensures repeatable movement, speed, and duration. The following screen sizes are appropriate: wheat, 2.0 mm slotted; for barley, 2.5 mm and 2.2 mm slotted; for sorghum, 2.0 mm slotted (wheat screen); for sunflowers, 2 mm round; for chickpeas, top 3.97 mm slotted over bottom 2 mm slotted; and for canola, top 2.58 mm round over bottom 1.00 mm round.

Figure 11 Agtator equipment for sieving grain.

Visual Examination and On-the-Spot Instrumental Analysis

Traditional methods of analyzing contaminants involve visual inspection, and this approach is still the best with respect to providing an immediate outcome and requiring no expensive equipment. However, this approach is subjective and highly dependent on the experience of the inspector. This expertise is acquired and maintained by ongoing training, the use of illustrated manuals and actual samples, requiring ongoing monitoring to ensure the standards are applied consistently. By this approach, grain samples are first evaluated visually at the site of grain receival, and then a representative portion may be sent back to a regional laboratory for a second cross-reference assessment. In addition, a further portion may be presented to buyers of the grain for their additional evaluation. The identification of the species of insects is also an important part of this process, because the various insect species differ in the severity and consequences of infestation.

The immediate detection of serious contaminants is critical at the time of delivery, so that defective grain loads are not combined with sound grain, as this might downgrade the grain to which it is added. Subsequent analysis in the laboratory provides results too late to prevent damage of a large grain consignment by, for example, the incorporation of a relatively small load of grain that is tainted or insect infested. On-the-spot analysis is thus critical.

It has become usual for visual inspection to be complemented by on-the-spot testing to provide objective results for specific critical aspects of contamination. Image analysis has great potential for replacing the subjectivity of human involvement by analysis of the image of grains and contaminants provided by a television camera. However, the introduction of image analysis is a slow process due to the expense and technical input required to develop methods and monitoring procedures.

NIR analysis has been used to detect the presence of insect infestation, probably due to the ability of this spectroscopic method to detect the distinctive presence of insect protein and/or chitin. The use of NIR methodology has the potential advantage that NIR equipment is already in routine use to determine moisture, protein content, and oil content, but the NIR units in routine use may not be adequate for more complex analyses. Ultraviolet light inspection provides an immediate means of checking for rodent urine, which fluoresces with a blue-green color (*see* **Appendix**: Test Methods for Grain and Grain-Based Products; AACC Method 28–85). Rapid immunoassay kits are now available to detect and quantify a range of chemical contaminants, aflatoxins, and damage from sprouting.

Analysis in the Laboratory

Contaminant identification may continue by visual examination at a regional or central laboratory, where a higher level of expertise may be expected of the inspectors. There is also a role for image analysis and sophisticated NIR equipment at a central site, where the volume of samples would warrant the expense and need for operator expertise. A wide range of laboratory methods is available for the detection of specific contaminants. For example, the AACC Methods provide many standard procedures in section 28 "AACC Method Group" (*see* **Appendix**: Test Methods for Grain and Grain-Based Products). Laboratory methods include gas or liquid chromatography to analyze for agricultural chemicals and ELISA immuno-assays for many contaminants, especially aflatoxins.

Avoidance of Contaminants

Purity of Seed Sown

An obvious source of contaminants is the seed originally sown. If it contains foreign seeds, these are likely to multiply and downgrade the harvested grain. Additional risks include the presence of diseased seed, which will lead to the spread of diseases during growth. It is thus important to obtain seed of guaranteed purity at the time of purchase.

Farm Management

Use of "best farm-management practices" includes cleaning and calibrating of harvester and sowing equipment before use, proper preparation of fields before sowing, ensuring that the crop is mature before

harvesting, and storage of the grain so that it does not become contaminated. During growth of the crop, weeds must be controlled. In addition, it is valuable to use crop rotations as "bio-fumigants" to avoid the buildup of microbial spores in soils.

Quality Assurance Methods

All these methods of contaminant avoidance should be combined for implementation via a system of quality assurance, to provide systematic recognition of potential hazards, intentional approaches to avoid the hazards, and records to indicate how and when the preventive measures were taken. This approach extends beyond the farm, to involve, for example, the use of traceable and repeatable methods of appropriate farm practices, working only with companies that are themselves quality-assurance certified.

International Regulations on Contaminants

International regulations on many food matters are administered by parts of the Codex Alimentarius. The Codex Committee on Food Additives and Contaminants (CCFAC) establishes or endorses maximum or guideline levels of contaminants in food and animal feed, as well as dealing with food additives and naturally occurring toxicants. CCFAC is developing risk-analysis approaches to be applied to all foods. The resulting document is the General Standard for Contaminants and Toxins in Foods. Further details of the latest developments are available at the USDA website: www.fsis.usda.gov/oa/codex/fac.htm.

Future Prospects

Traditionally, the presence of contaminants of any type in a grain consignment has prompted a reduction in its market value, because any variation in appearance can provide grounds for bargaining and for price reduction. More recently, there has been a growing awareness that some defects and contaminants may have relatively small financial consequences. In some instances, the economic effects can readily be assessed. For example, the presence of 2% screenings (by weight) at a 5% reduction in price would be a worthwhile bargain, if the cost of cleaning is more than covered in the price difference. Similar considerations apply to other innocuous contaminants, if their dimensions make them easily removable. Another approach to overcoming such problems may involve the intelligent blending of diverse grain samples. Relatively simple research activities can establish the extent of economic penalties for the presence of one grain type as a contaminant in another, e.g., oilseed in cereal or the reverse.

There is a continuing need for more effective methods of analysis to characterize and quantify the presence of contaminants in grain deliveries at the point of receival and during grain handling. New screening methods should preferably be deployable on-the-spot and be nondestructive of the grain. Most of all, they need to be cost-effective, the cost of deployment warranting the benefits, and the risks thereby avoided. Detection of contaminants by image analysis is likely to increase in its application. We can expect that large grain sorters will be placed into grain-storage sites and cleaning facilities.

Increases in quality demands will mean the need to increase the efficiency of detection and measurement requirements at the receival point. In summary, these new methods must be rapid (taking less than 5 min), easy to operate with minimal operator skill required, nondestructive and cost-effective, being able to operate in a wide range of temperature variation, under dusty conditions, occupying minimal bench space . . . but the fulfillment of these requirements is a "tall order."

COTTONSEED

E Hernandez, Texas A&M University, College Station, TX, USA

Introduction

Most varieties of cotton (*Gossypium hirsutum* L., *G. aboreum* L., *G. barbadense* L., or *G. herbaceum* L.) are grown mainly in warm climates around the world. Over 98.5 million tons (Mt) of cotton were produced worldwide in 2001–02 and over 33.6 Mt of cottonseed. Cotton is grown for its fiber (over 80% of its value) and the seed is used mostly for oil recovery and feed. Whole cottonseed can be fed to dairy cattle, and the meal resulting from oil extraction is fed primarily to ruminants and, in limited amounts, to poultry and swine.

Traditional varieties of cottonseed contain gossypol, a yellow-green polyphenolic compound considered toxic to man and monogastric animals (Figure 1), reportedly affecting the heart, liver, and reproductive organs. It has been used in China as a male contraceptive but the practice was abandoned because of permanent side effects. Gossypol is dispersed in the plant as deposited structures or "glands," which can be seen as black specks in the stems, leaves, and seed (Figure 2). The glands in the seed are ovoid structures containing 35–50% gossypol and are 0.025–0.178 mm in diameter. These gossypol glands are difficult to break by mechanical means, but heat generated in extraction of oil by pressing, binds gossypol to protein, turning it nontoxic. Switching to solvent extraction with hexane, where no appreciable heat is generated, increases the free gossypol content in the meal over ten times.

Raw cottonseed kernels may contain 0.6–2.0% free gossypol. The Food and Drug Administration in the US (FDA) limits free gossypol in human food products and ingredients at 450 ppm, and the Protein Advisory Group of the United Nations Food and Agriculture Organization (FAO) and World Health Organization (WHO) has set maximum guidelines of 600 ppm for free gossypol and 12 000 ppm total

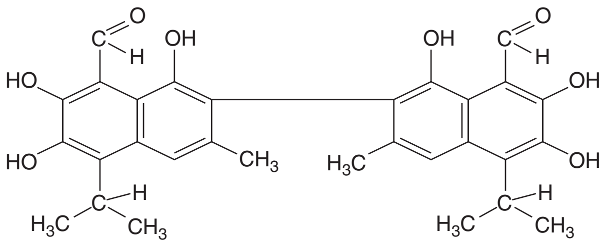

Figure 1 Gossypol.

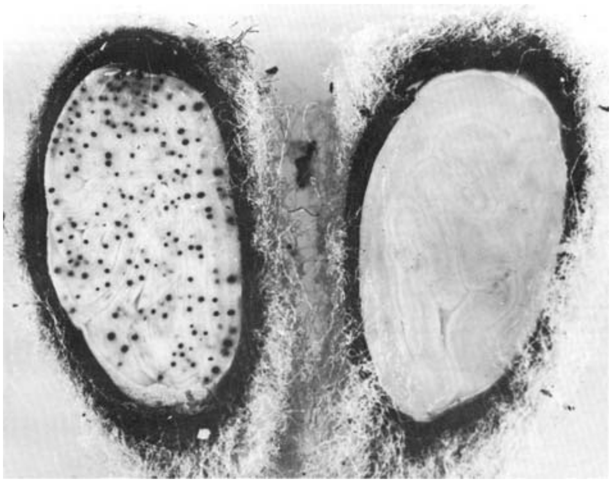

Figure 2 Cross-section of glanded cottonseed (left) and glandless seed (right). (Data from Miravalle RJ (1972) *J. Am. Oil Chem. Soc.* 49: 24–26.)

gossypol. The feed industry in the US set limits for free gossypol levels in poultry diets at 100 ppm maximum for broilers and 40 ppm for laying hens.

Removal by mechanical separation of the gossypol-containing glands has also been reported. Also addition of iron salts, such as ferrous sulfate, which bind the gossypol in feeds and render it biologically inactive, is practiced in some countries.

Solvent extraction with hexane of cottonseed oil, commonly used commercially, removes only small amounts of gossypol with the oil. However, extraction with more polar solvents is effective in removing gossypol. Examples of polar solvents used include aqueous acetone, a mixture of acetone and hexane, and sequential extraction with hexane, aqueous acetone, and anhydrous acetone. Blends of methylene chloride and hexane-acetic acid have also been used. These solvents are not widely used commercially.

Techniques have also been reported that mill cottonseed in the presence of hexane and then remove the intact, heavier gossypol glands by the liquid cyclone process. Also, an air classification process has been developed to separate intact gossypol glands from solvent-extracted ground flour.

Glandless Cottonseed

Some of the first studies on the development of glandless cottonseed in the US were done in the early 1950s. These studies described that selection of plants from the "Hopi Moencopi" variety could result in almost complete elimination of pigment glands from leaves and bolls. When crossing Moencopi with upland cotton varieties (*G. hirsutum*), it was found that glandless seed appeared in later segregating generations. Production of glandless cotton was first conducted in Iguala, Mexico in 1960.

Basically two genes, *gl-2* and *gl-3*, in the plant are found to control the production of gossypol pigments in the seed. When present in the homozygous recessive condition (*gl2gl2–gl3gl3*), all parts of the plant aboveground, including the seed, have no pigment glands. The presence of pigmented glands can be easily seen as black specks by cross-sectioning a seed (Figure 2).

Recently, the value of the whole seed as cattle feed has increased making it less profitable to extract the oil and sell the meal. In some cases cottonseed is left at the gin in exchange for ginning and baling services. Sometimes glandless cottonseed is considered to produce fiber of lower yield and quality than traditional "glanded" varieties. Some studies have shown that the glandless factor in itself does not decrease fiber yield or quality as long as care is taken to prevent weed and insect infestation.

Gossypol is regarded also to be a natural insecticide. Reports show that glandless cotton attracts more insects than glanded varieties. Entomology studies have shown that cotton bollworm (*Heliothis zea* Boddie), tobacco budworm (*H. virescens* F.), pink bollworm (*Pectinophua gossyprella* Saunders), and lygus insects prefer glandless cotton. It is generally recognized that glandless varieties require closer supervision to intercept and control insect infestations.

Processing and utilization of glandless cottonseed was reported in the early 1960s in the US. Glandless cottonseed oil and meal were evaluated in poultry broiler and layer rations. Glandless cottonseed meal was found nearly as effective as soybean meal in achieving broiler gains and did not produce the green yolk discoloration in eggs commonly experienced with feeding glanded cottonseed meal.

The first commercial glandless cotton variety was a storm-proof, boll-type cotton. It was evaluated in farm-scale trials and made available for commercial planting in the late 1960s in the US. Commercial sale

of glandless cottonseed began in the early 1970s, with FDA approval. In 1976, under title 21 (Food and Drugs) of the Code of Federal Regulations, sale of glandless cottonseed kernels and cottonseed flour as food additives was allowed. It included restrictions on gossypol (450 ppm). In 1978 the National Cottonseed Products Association (NCPA) in the US established grades of glandless cottonseed products: class A, to contain not more than 400 ppm of total gossypol; class AA, to contain not more than 100 ppm total gossypol; and class AAA, to contain not more than 10 ppm total gossypol. Glandless cottonseed kernels started to be sold for use as snack foods, in baked goods and in soft candy.

Research and production of glandless cotton for food and feed is also reported in Europe, Africa, and Asia. Some US cotton varieties were adapted to African crops. Development and study of some Egyptian varieties of glandless cotton have also been reported. From studies done in the Ivory Coast, it has been suggested that glandless cottonseed cultivation and oil mill processing is more economically viable in that part of Africa. Conditions there may be better for glandless cotton considering that in larger industrialized countries other competitive oil seed proteins are more readily available. An additional advantage is that large, isolated land areas can be dedicated to this crop and less problems of cross-pollination would be encountered.

Processing and Products

Other than gossypol content very few differences are found in glandless compared with glanded cottonseeds. Evaluations of eight varieties each of glanded and glandless cottonseed were reported (Table 1). Amino acid profiles were similar for glanded and glandless seed. The storage and processing characteristics of glandless and glanded cottonseed are also reported to be essentially identical with regard to development of free fatty acids, moisture levels, and refining losses in the crude oils.

No major differences were encountered either in solvent extraction of glanded versus glandless cottonseed. Extraction rates of oil from glandless cottonseed flakes are about the same as from glanded flakes, using commercial hexane. It has also been suggested that glandless cottonseed can also be a source of a new type of lecithin. Cottonseed has the highest content of phospholipids after soybeans, present at ~2.2% in the oil, but due to gossypol presence it was not commercially viable. Currently, the major commercial source of lecithin is soybean oil. Composition of cottonseed phospholipids consists of phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositiol (33%, 22%, and 37%, respectively) and is considered more oxidatively stable than soybean phospholipids due to lower content of unsaturated fatty acids.

One of the main advantages of milling glandless cottonseed is that it simplifies direct solvent extraction. Current commercial practice of refining glanded cottonseed oil requires that the oil be refined in its miscella state (oil–hexane solution) right after extraction. This is necessary because if the solvent is removed from the oil prior to refining, the color

Table 1 Comparative analysis means of eight varieties each of glanded and glandless cottonseed and their products[a]

fixes into the oil and is very difficult to remove in subsequent bleaching operations. This means the equipment in refining of miscella has to be explosion-proof, which is more expensive and more difficult to maintain. This is no longer the case with glandless seed processing, where binding of gossypol (by cooking and hard press or prepress) or miscella refining become unnecessary. The oil from glandless seed is in lighter colored oil and the meal has greater amounts of soluble protein. Protein solubility of processed glandless cottonseed flakes or press cake has been reported to be higher than that of glanded seed (89.6%) compared with 84.8% for extracted flakes, and 59.3% for press cake.

Advantages of processing glandless cottonseed over glanded seed include:

1. reduction in electrical energy used for flaking;
2. elimination of prepress operations with larger solvent extractors with lower maintenance costs, and reduction in processing energy;
3. since there is no color setting problem, crude cottonseed oil can be held longer in storage;
4. elimination of more dangerous miscella (oil-solvent solution) processing or on-site conventional refineries;
5. lower refining loss of glandless seed oil due to reduced use of alkali to eliminate color;
6. reduction of bleaching earth needs; and
7. marketing of a light-colored, gossypol-free oil.

Some emulsification problems have been reported in refining desolventized crude due to higher concentration of lecithin.

There are some drawbacks when switching to glandless crops; varying levels of gossypol can exist among individual seeds from the same plant. It is also difficult growing large acreages of glandless cottonseed, without cross-fertilization by windblown or insect-carried pollen of glanded varieties. In order to preserve the variety and seed lot purity in the production of glandless cottonseed products, it is important to monitor both, cross-fertilization from cotton plants in nearby fields and reversion to the glanded condition during successive plantings due to fertilization between heterozygous plants. Furthermore, segregated handling of glandless cottonseed in gins and oil mills can also be costlier. As a result large cottonseed processors may be hesitant to handle glandless cottonseed and dedicate separate processing facilities.

Foods Uses

Several food uses of glandless cottonseed kernels have been reported as well as applications on the use of glandless cottonseed blended with other foods. Even though glanded cottonseed is not considered suitable for human consumption, there have been cases where cottonseed flour with bound gossypol has been used in nutrition intervention feeding products, such as Incaparina in South America.

Food products from glandless cottonseed include whole roasted seeds, flour, protein concentrates, and isolates. From these products many foods were reported to be prepared. The technologies for the production of high-protein products have been well established and apply similarly to all vegetable proteins. Specific technologies were developed for the production of cottonseed protein products that were later applied for processing of other vegetable proteins like soybean.

The preliminary steps in preparing glandless cottonseed products are similar to the process used with glanded cottonseed, i.e., ginned cottonseed is first cleaned to remove dirt and other impurities, conditioned, de-hulled, and separated to produce kernels. The kernels may be size-sorted and the larger particles roasted and color-sorted. The whole kernels are separated for roasting or conditioning. The smaller or broken kernels may then be further conditioned, flaked, and solvent-extracted for production of flours, concentrates, and isolates.

Whole glandless cottonseed kernels are prepared either for direct use as whole nut substitutes or for food ingredients. These are also used in the production of high-quality flours and food protein concentrates or isolates. The use of glandless cottonseed kernels for the production of nutlike products by means of various roasting methods has been reported, including dry roasting at several temperatures, roasting under vacuum followed by steam injection, pressure steaming followed by oven roasting, and deep fat frying in various oils (including corn, cottonseed, peanut, safflower, soybean, and sunflower oils). When the main product is to produce high-protein flours, less care needs to be taken to minimize breakage during de-hulling.

Glandless cottonseed flour can be prepared by extracting de-hulled glandless seed flakes with hexane. The extracted flakes are then desolventized and ground to a desired mesh size. In the production of cottonseed concentrates, the defatted flakes are re-extracted with acidified water or ethanol to remove the soluble sugars and flavor compounds, and dried to produce protein concentrate. A spray dryer can also be used in preparing concentrates where the defatted flakes are ground prior to extraction. Concentrates have been prepared from flour by a dry air classification method and by acidic water extraction. Figure 3 shows a simplified diagram of the process to be used

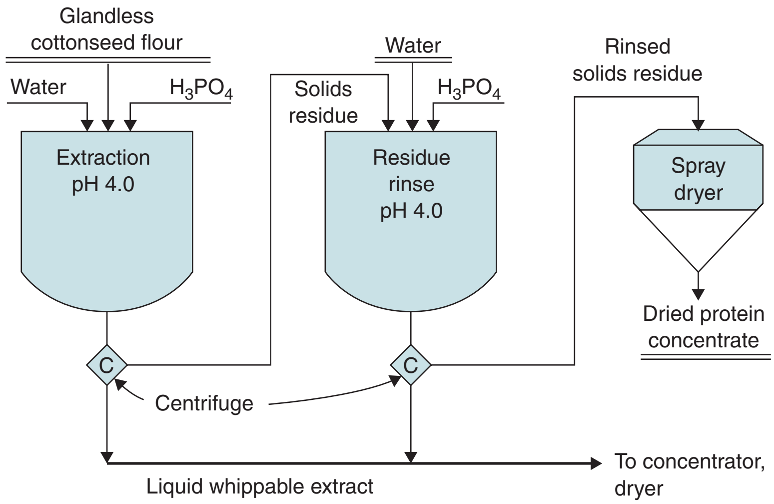

Figure 3 Protein concentrate production from glandless cottonseed. (Data from Lusas EW and Jividen GM (1987) *J. Am. Oil Chem. Soc.* 64(6): 839–854.)

to generate protein concentrate from glandless cottonseed.

Three major techniques have been reported for making glandless cottonseed isolates. These isolates can be conventional protein isolates, storage proteins (SP) (soluble at high and low pH), and nonstorage proteins (NSP) (soluble at near neutrality):

1. Ground flour is first extracted with dilute alkali (at pH 10) and the insoluble residue removed by continuous centrifuging or decanting. The clarified liquor is then precipitated at one pH (5.0). The resulting solids are concentrated by centrifugation and then dried to produce a mixture of storage protein and nonstorage protein.
2. In the "selective precipitation" procedure the protein is precipitated with alkali at a pH 10, the solids are then separated by centrifugation. The solids in the liquor are also precipitated at pH 7, and the storage protein curd removed by centrifugation and then dried. The liquor is further acidified to pH 4 to precipitate the NSP, also removed by centrifugation and then dried. The soluble matter remaining in the whey is then removed by either the selective extraction or selective precipitation method. A relatively pure storage protein fraction, containing over 90% protein (dry weight basis), can be prepared.
3. The "selective extraction" procedure consists basically of leaching the proteins soluble with water at neutral pH, where the solids are then centrifuged out. The liquor is then acidified to pH 4; this results in a precipitated protein curd. The curd is dried to produce an NSP isolate. The solids from the original water leaching are then solubilized in alkali at pH 10 and centrifuged to remove insolubles. The liquor is then precipitated at pH 7 and the resulting curd is concentrated and dried to produce an SP isolate.

A patented process for the preparation of glandless cottonseed protein concentrate from solvent-extracted flour using industrial membranes has also been used. Defatted flour is sieved through an 80-mesh screen to break up any agglomerates and remove hull particles, and suspended in acidified water at pH 4.0–4.5. This solution is passed through an ultrafiltration membrane (100 000 MW cutoff) and the solids retained are either dried directly or neutralized before drying. The liquid fraction permeate may then be passed through a reverse osmosis membrane to concentrate the soluble solids and to recover water which may be reused in the process.

Feed Uses

Glandless cottonseed has been reported to be suitable for monogastric animal feed not just for its lack of gossypol but also for higher available energy. The lower heat treatment required for glandless cottonseed during milling is reported to degrade less protein than the prepress method normally used with glanded cottonseed. Commercial glanded cottonseed meal intended for poultry feeding usually receives considerable heat during processing to intentionally bind the gossypol. Also in order to increase the amount of glanded meal gossypol, addition of iron to the meal is used to inactivate gossypol. In the cases of glandless

cotton meal, it would be expected that lower heat treatment needed for glandless cotton would have beneficial effects in the protein availability and quality of the meal. Some heat pretreatment of the meal is still recommended, however, before hexane extraction, to improve protein efficiency. Heating glandless cottonseed with 12% added water for 10 min at 82°C, followed by 105°C for 20 min before hexane extraction, was reported to appreciably increase broiler weight gains when compared with glanded cottonseed feed. It has also been shown that meal from glandless cottonseed had an equal protein availability to soybean meal in supporting chick growth. Feed trials with glanded cottonseed meal with swine, catfish, fish, and shrimp have also been described.

CULTURAL DIFFERENCES IN PROCESSING AND CONSUMPTION

J M Jones, College of St. Catherine, Arden Hills, MN, USA
C I M Jones, Minneapolis, MN, USA

Most cultures use a cereal grain as a staple. These staples have a myriad of uses throughout the day from appetizers to desserts. In some cases they are eaten alone and may be the main course of the meal. When eaten in combination with other foods, they can remain the main course or can act as carriers, as bread in sandwiches, noodles in pad thai or rice in pilafs, congees, or risottos. Some cereal-based foods are common to all cultures – a flat or griddle-cooked bread; pastas, noodles, or dumplings; gruels and porridges; snacks, biscuit (cookie), or crackers. While there is commonality, there can also be great differences imparted by the base grain and the added ingredients.

Even with the same base grain a number of factors affect the nutritional composition. Even within the same cultivar factors such as climate, soil, storage time and conditions, processing, and maturity at harvest affect the nutritional value. Grains may be minimally processed or highly pulverized and/or treated by intense heat. They may undergo germination or fermentation processes that either increase or decrease their nutritional content. Other ingredients may increase or decrease their nutritive contribution. The frequency with which the foods are eaten, the accompanying foods, and the occasion all have an impact on overall diet quality.

The actual nutritional impact depends on the nutritional status of the population, their reliance on a particular grain as a staple, and particular processing methods in that country. This article discusses the place of grains in the diet, the specific grain, and whether the cultural practice of consumption of grains, either eaten customarily as whole grain or refined, can have a significant impact on the diet.

Cultural Differences in Processing and Consumption – Energy Requirements

Cereals can provide well over 50% of both energy and protein in parts of the developing world. In the developed world, particularly the USA, cereals provide a much smaller percentage of energy and are not relied on for protein except in subgroups such as vegetarians.

Highly refined grain offers more available carbohydrate and slightly more calories than unrefined grains. Furthermore, antinutrients present in the outer layers of grain may inhibit amylases and proteases diminishing the total number of calories available. This can be a particular problem in areas where sorghum is a staple. In countries where calories are in short supply, refined grains may be beneficial. In developed countries where obesity threatens, the inclusion of whole grains with their slightly less available carbohydrate may be advantageous.

Cultural Differences in Processing and Consumption – Protein

In terms of protein, each cereal offers distinct nutritional characteristics. These become important only if the staple is relied on as a major protein source. For example, oats offer a higher protein content than other grains and an amino acid pattern closer to the FAO standard than other grains. Historically, the high quality of protein from oats was once important in the UK and in parts of northern Europe. Similarly the high protein content of pseudocereal buckwheat provided important protein nutriture in parts of the former Soviet Union.

In most Western countries, protein quality and quantity is not an issue so cultural practices have little impact. However, for parts of the Indian subcontinent, Asia, and Africa, processing of cereals such as milling, fermentation, and cooking have important nutritional impacts. Milling may make protein more available and fermentation may improve biological availability of essential amino acids.

Fermentation and germination are important for improving the nutritional quality of grains. Fermentation, together with cooking and de-hulling, reduces the tannin of sorghum and millet. Since tannins complex with protein, they inactivate digestive enzymes and reduce protein digestibility. The presence of tannins in food can therefore depress growth and increase protein loss. Germination not only increases the synthesis of lysine and tryptophan, it also improves digestibility.

Cereals are incomplete proteins and have lysine as their most limiting amino acid. Corn protein is also

limiting in the essential amino acid tryptophan, while other cereals are often limiting in threonine. Throughout the world, the practice of combining cereals with pulses makes a complete protein, so-called protein complementarity. In reciprocal fashion cereal grains contribute methionine, which is deficient in legumes. A survey of national dishes from around the world shows the many interesting and unique ways that different cultures have chosen to complement the protein. These time-honored national dishes are popular for vegetarians around the world. Some of them are listed below:

- India/Sri Lanka – "rice pilaf," "dhal" (legume);
- India/Sri Lanka – "chapati," "dhal";
- Middle East – "pita" bread, "Hummus" ("garbonzo" bean/"tahini spread"); and
- China – "congee" (rice gruel), small amounts of meat, tofu, or fish.

Cultural Differences in Processing and Consumption – Carbohydrates Including Dietary Fiber

Starch and Sugars

Many processing and cultural factors have nutritional impacts on sugars and starches. Carbohydrate energy provided in large part by the starch may be more available when the bran and germ portions are removed or if people from a particular culture regularly eat very finely pulverized grain or products such as broken rice. This is important in areas where calories are in short supply.

Germination and fermentation of grains have two impacts on carbohydrates: (1) improved starch digestibility as amylases partially degrade starch and (2) decreased flatus as some indigestible sugars degrade.

The glycemic response of grain-based foods is affected by processing because accessibility of the starch to digestive enzymes is changed. Inclusion of low glycemic index foods has been shown in some studies to positively influence blood sugar control, blood lipids, and other chronic diseases.

Cultural practices with regard to processing affect the glycemic index. For instance, wheat made into porous bread is easily penetrated by the digestive enzymes and has a high glycemic index. Bread made by the sourdough process reduces glycemic index because of the pH lowering. Wheat as an *el dente* pasta has a still lower glycemic index because the compact structure is less accessible to digestive enzymes.

For rice, varietal preference as well as processing affects the glycemic response. Medium- to high-amylose rices, such as "basmati" preferred in India, have lower glycemic indexes. Glutinous rice used in Asia contains as much as 100% amylopectin and has a high glycemic index. Processing, such as parboiling to make converted rice and noodle making, tends to reduce the glycemic index.

Chemically modified starches which are used in many processed foods in developed countries have low glycemic responses. However, waxy cornstarch, which is 100% amylopectin, used in canned and frozen foods has a high glycemic index.

Processing can also impact whether or not a starch is digested and absorbed, e.g., forms of resistant starch. Grains which are minimally processed have slowly released carbohydrates and also show lower glycemic responses. High-temperature extrusion to make products such as corn flakes increases the amount of resistant starch. Resistant starch behaves nutritionally like dietary fiber, e.g., it is not absorbed in the small intestine and is fermented in the large intestine. More information is needed on the effects of various processes on the amount of resistant starch formed.

Fiber

Lack of adequate fiber has been associated with decreased gut motility and increased risks of heart disease, diabetes, and some types of cancer. For diets in developed countries, intakes of whole grains are low as are the extractions typically used for making flour-based products.

The degree of milling, or extraction rate, has a nutritional impact. Higher extraction rates are used in countries such as Norway, which regularly uses 80% extraction. The net result is a diet that has a higher dietary fiber and phytochemical intake from grains than when a low extraction rate is used, such as in the USA.

The cultural practice of including whole grains also impacts fiber nutriture. In Finland, regular use of breads and other products made from rye, oats, and barley and more frequent use of whole grains contributes to higher dietary fiber intakes than other European nations. In Mexico, traditional diets with high intake of whole meal corn tortillas and beans result in very high fiber intakes.

The grains which are frequently chosen in a culture also affects nutriture as different grains offer different fiber components, each with its own unique physiological characteristics. For instance, Germans and Scandinavians often choose rye. It contains a relatively high content of pentosan, a fiber with an arabinoxylan backbone containing small amounts of glucose and ferulic acid. Wheat, more frequently used in the

US and southern Europe, contains fewer pentosans than rye. Northern Europeans also use barley and oats. Their β-glucans are of interest because of their ability to lower serum cholesterol and attenuate blood glucose. Therefore, the consumption of these grains and brans from these grains is encouraged for heart patients and diabetics.

In countries of Africa exceedingly high levels of dietary fiber, especially fibers from sorghum with its high tannin content, have negatively impacted mineral nutriture. Inclusion of some types of hull material can irritate the bowel. Oat hulls, for example, have razor sharp pieces that can actually cut gut tissue.

Cultural Differences in Processing and Consumption – Micronutrients

Most vitamins, minerals, and phytochemicals reside in the bran and germ. Thus, the cultural practice around the amount of the diet consumed as whole grain and the degree of milling affects the micronutrient contribution of grains. When the cultural practice is to consume more whole grains, the amount of micronutrient ingested goes up. However, ingestion of micronutrients does not always equal absorption. Tightly bound microcomponents may act locally on the gut but may not be absorbed. Milling reduces the level of all micronutrients but may release some and make them more absorbable. For strongly bitter grains such as sorghum, milling confers consumer acceptability. Over-milling or a high degree of extraction removes the aleurone layers and germ-rich vitamins and minerals and other phytochemicals.

Cultural processing practices can affect the availability of micronutrients. For example, without heat treatment of rice bran, lipases will destroy essential fatty acids, fat-soluble vitamins, and antioxidants in the bran. However, severe heat treatments may destroy vitamins, bind nutrients, or even initiate rancidity, which could decrease fat-soluble vitamins and produce free radicals that could have adverse effects on a number of vitamins. Liming of corn releases its bound niacin.

Several processes such as enrichment and fortification are used in many countries replacing vitamins and minerals lost during milling. Niacin enrichment of corn and flour helped eliminate pellagra in southeastern US. Folate enrichment of grain products has reduced birth defects such as spina bifida.

Enrichment of rice by adding a vitamin-rich talc has made an important nutrient contribution. However, enrichment's effect may be nullified due to certain cultural practices such as washing rice prior to cooking or cooking in large amounts of water, which is discarded.

In areas where food availability is limited, the actual grain chosen and whether the grain is enriched can be critical. For example, in areas selecting unenriched milled rice as a staple, peripheral neuropathy and other symptoms indicative of early stages of beriberi may be present in the population. Such symptoms are seen in parts of Indonesia, where steamed white rice is used and few other thiamine-containing foods are eaten.

Fermentation and malting can change nutrient quality. Vitamin B often increases with fermentation, although the actual amount depends on the starting grain and the particular process. For example, in the preparation of "kaffir" beer (from maize), thiamine levels are virtually unchanged, but riboflavin and niacin contents almost double. The malting or germination of grains and pulses as practiced in certain parts of the world such as India increases vitamin C and phosphorus availability.

Cultural practices surrounding grain choice and processing can affect mineral status. Tannins, phytates, and other ligands in grain bind iron, zinc, and other metals thereby contributing to mineral deficiencies. High concentrations of tannins and cyanogenic compounds in grains such as sorghum can adversely affect the thyroid and contribute to the incidence of goiter. Milling removes much of the tannin and phytate or pulverizes the grain, making absorption of some minerals more likely.

Fermentation can affect phytic acid and hence mineral status. Thus, cultural practices around fermentation affect the amount of time the phytase enzyme is allowed to degrade phytate with longer fermentations improving mineral status. For example, in the early 1970s it was noted that many adolescent males in poor, rural parts of the Middle East failed to mature sexually (a syndrome called hypogonadal dwarfism). In this case the diet was comprised of nearly 85% whole-wheat pocket bread. The short fermentation coupled with high-temperature baking failed to allow enough phytase reaction; so the zinc remained tightly bound by the phytate and unavailable to the young boys.

Cultural Differences in Processing and Consumption – Toxic Components

In addition to tannins and phytates, cereals and other plant foods may contain significant amounts of toxic or antinutritional substances. Milling removes a number of these:

- Protease and amylase inhibitors occur widely in cereal bran, which is lost during milling. They may be further reduced during fermentation but are not greatly affected by heat.

- Saponins, noted for their hemolytic activity, can cause growth inhibition. Interestingly, recent evidence indicates that these compounds may have some anticancer activity in the colon.
- Mold toxins found in all parts of the grain may be partially removed. Further reduction of mold toxins such as aflatoxin B1 occurs during fermentation because the lactone ring is opened.

Cultural Choice of Specific Grains and Their Effect on Nutriture

The remainder of the article will focus on each grain, how it is processed and consumed and what nutritional implications result from the selection, processing, and preferred methods of consumption.

Rice

Rice is used throughout the world in diverse ways from Chinese stir-frys, Spanish "paellas," Japanese "sushi," Indian "biryanis," Thai "salads," Turkish "pilafs," Italian "risottos," Senegalese "yassas," Norwegian rice pudding to American "gumbos." Many of these dishes use white rice as the basis for important nutrients and energy, but rely on the other ingredients to contribute more nutrients and phytochemicals to the total diet.

Colored rice, such as black rice ("wehini"), used by Asian cultures have more antioxidants and nutrients than some other varieties. Some varieties are said to have medicinal properties such as a "body-strengthening" fraction or "nerve rejuvenating" function in paralytic conditions.

Wild rice, technically not a true rice, is comparable in nutritional quality to oats. It is almost always eaten as a whole grain so there is very little nutritional loss from processing wild rice.

Rice and wild rice are often the grain of choice for those allergic to wheat or those with gluten enteropathy (celiac sprue) where sufferers must avoid wheat and its relatives, rye, barley, and any grains that might have been contaminated by being processed on the same line as any of the aforementioned grains.

Broken rice During the milling of rice some grains are broken, or "damaged." These broken pieces are separated from the intact kernels. A grain of broken rice retains its high energy content but has a higher glycemic index than unbroken rice because the gut enzymes have ready access to the starch. In parts of Africa, broken rice is preferred because of its cheaper import price and fast uniform cooking. Broken rice is also used to make rice flour and rice noodles.

Broken rice can be processed to improve nutrient intakes. Vitamin A deficiency in children is common in many countries where the staple is rice. Broken rice grains can be made into a dough fortified with vitamin A and then reconstituted into rice-shaped kernels that have the same taste and texture as regular rice. Because the majority of the added nutrient is inside the shaped kernel, it is protected from oxidation, washing, and cooking. This technology also holds promise for other fortifiers such as iron, folic acid, and other micronutrients not present in normal rice.

The development of golden rice using biotechnology to add vitamin A is another process with potential. Addition of vitamin A is one tool to help prevent the WHO-estimated 250 000 to 500 000 cases of blindness due to vitamin A deficiency in children annually.

Rice is also made into processed food. It is puffed for use as breakfast cereal and rice cakes. They are popular with dieters in developed countries because of their low caloric value, but they tend to have a higher glycemic index than some other forms of rice. Those trying to avoid wheat also enjoy these. In Asian countries, rice-based snack foods are popular. In Japan, they account for $\sim$10% of total rice consumption. Other Asian countries eat processed rice products, primarily noodles. In terms of nutrition, the glycemic index may change and thiamine may be unaffected or completely destroyed depending on the temperature used in the process.

Wheat and Its Parent Grains

Wheat is important in most Western cultures and is basic to most breads, rolls, crackers, cookies, biscuits, cakes, doughnuts, muffins, pancakes, waffles, noodles, pie crusts, ice cream cones, macaroni, spaghetti, puddings, pizza, and hot, and cold breakfast foods. It is also used in baby foods, and is a common thickener in soups, gravies, and sauces. Germ, bran, bulgur, and malt are additional types of wheat products.

The largest nutritional impact is determined by the amount of whole wheat and refined wheat utilized and whether the refined grain is enriched or fortified. The glycemic index of wheat products can also be affected by the process and the end product. For example, bread from a sourdough method reduces the glycemic index over ordinary bread. Addition of grain particulates also slows starch digestion.

Processing and cooking methods affect the nutrition of products. Here are some examples:

- precooking and parching of bulgur before cracking, not only enables its quick cooking, it reduces the phytates;

- steaming of breads and dumplings, widely practiced in parts of Asia, minimizes Maillard browning products and heat-produced compounds such as acrylamide;
- steaming of fermented flat breads such as "injera" from Ethiopia slightly increases the availability of lysine; and
- frying of wheat noodles to make "ramen" and "chow mein" noodles increases the fat and saturated fat content.

Spelt, kamut, and teff Most of the nutritional qualities of spelt and kamut are the same as their wheat parents and processing has the same impacts. However, the protein content of spelt was consistently higher (18–40%) than that of the hard red wheat; however, lysine content was lower. The use of spelt and kamut is common in some African populations. It is very limited in the USA although some in the health-conscious market are trying to bring it back.

Teff is used where it is grown in East Africa for the slightly spongy, slightly sour griddle bread called injera. Injera comprises approximately two-thirds of the diet in Ethiopia and Eritrea. Teff has very high calcium content, and contains high levels of phosphorus, iron, copper, aluminum, barium, and thiamine.

Sorghum and Millet

Sorghum and millets are used as staples in parts of Africa and Asia. In some African countries, 45% of the total annual calorie intake from cereals comes from these gluten-free grains. Both millet and sorghum have tannins in the outer layers that can inhibit some protein utilization, but some sorghums contain amounts that can negatively impact nutrition status of those heavily relying on this staple. Removal of the outer layers by an abrasive mill increases storage, acceptability, and nutritional profile. However, the best nutritional quality occurs if only the outermost bran layers are removed retaining the germ and the aleurone layers intact.

Processing sorghum prior to use improves acceptability and digestibility. Soaking and cooking, especially in an acid medium, also aids cooking since the starch in these grains is slow to hydrate. Both processes improve digestibility. Other processes such as flaking, precooking, steaming, roasting, popping, or puffing making into "roti" or chapati improve the character of starch. The heat treatment not only imparts improved starch digestibility, it also contributes a highly crunchy texture and desirable flavor. Both the whole and polished grains and flours are used.

"Millet" is prized for its protein content, but not all varieties offer the same nutritional advantages. In India and parts of Africa, these differences may have dietary significance.

Pretreated millet grains are used for development of weaning and supplementary foods for school and preschool children. The pretreatment improves nutrition.

Barley

Barley has been used as human food since Etruscan times as a porridge. It is still used by many cultures and has remained an ingredient in soups, particularly those from Scotland and Eastern Europe. Patent barley is used as a commercial thickener and as baby cereal. In many cultures wheat or other staples have replaced barley but its use remains in other cultures. For example, Tibetan monks prepare "tsampa," a porridge made with toasted barley and blended with yak butter and tea.

The rich nutrient contribution of barley fails to help most human populations because it is used much more often in animal feeding. There has been some effort to increase its contribution to Western diets because its high soluble fiber content lowers serum cholesterol and helps control blood glucose. In this case pearling has less impact than milling of other grains as the important β-glucan is distributed throughout the grain.

Oats

Oats is still widely used in Ireland and Scotland, Finland, and parts of North America. Hot and cold breakfast cereals with oats as a base form well over three-fourths of the uses. The remaining 15% are used as oat flour or in snack products such as granola bars, breads, muffins, and cookie mixes.

The milling of the oats into steel-cut oats, rolled flakes, quick and instant flakes, oat flour, and oat bran can affect the nutritional contribution of this cereal. The size of piece and the degree of processing can all impact the glycemic index of the food. For example, instant oats have a much higher glycemic index than steel-cut oats. Using the bran alone can concentrate the cholesterol lowering β-glucan making it easier for physiologically important levels to be eaten in a normal serving of food.

In Western countries, interest in oat products has increased recently because of their documented health properties including cholesterol lowering of the β-glucan, important phytochemicals, and plant estrogens. This has led to the increased introduction of a number of oat cereals and breakfast bars.

Rye

Rye (*Secale cereale* L.) is grown and used primarily in northern climates. It was central to peasant diets as breads in these regions until the eighteenth century and is still used in, for example, Scandinavia, especially Finland, Russia, Germany, Poland, Ukraine, Belarus, and other countries of the former Soviet Union, where traditional rye sourdough and pumpernickel breads were principally used as the staple. However, the actual amount of rye eaten has declined in many countries. Health movements in parts of Scandinavia have rekindled interest in rye flakes and other breakfast cereals and rye products. Rye crispbread continues to be popular.

Processing has an impact on the nutritional offerings of rye. Rye breads produced in northern Europe are usually whole grain or use a high rye flour extraction rate. In contrast, in the USA most rye bread uses a low extraction rate and molasses or other coloring agents. So there is great difference in the fiber and sterol contribution from rye in various countries. Only the higher extraction and whole grain breads will harvest some of the benefits of rye including:

- a feeling of fullness and satiety,
- protection of the cells of the colon,
- binding of bile acids to aid in lowering cholesterol,
- control of blood sugar,
- improving bowel function, and
- provision of lignans with their phytoestrogen activity.

Maize

Maize is a staple in parts of Central America, Africa, India, and China. It is either used alone or in combination with other foodstuffs. For example, in Indonesia, corn is consumed as a primary staple food for at least major parts of the year before the main rice harvest. In other parts of Asia maize is combined with rice or millet, taro, sweet potato, and wheat. In Africa, maize is combined with millet, sorghum, yams, and sweet potato. Eastern Africa's "ugali" and southern Africa's "mealie-meal," "nshima," and "sadza" are usually made from maize.

Maize continues to be important in the Americas and processing can have significant nutritional impacts. When corn is placed in a solution with wood ash and boiled, the product is hominy or, in Mexico, "pozole." It may also be dried and processed into various products such as grits or "masa," which ultimately end up in gruel or as a meal for such products like corn tortillas. This alkaline process destroys vitamin B, particularly thiamine.

Some corn is dry-milled and used to produce breakfast cereal and snack foods; corn meal is used in corn bread, hush puppies, and pancake, and bakery mixes; and masa flours form the basis of corn chips, tostadas, taco shells, tortilla chips, and other Mexican foods. The predominant form of corn meal is de-germed and so it does not offer the benefits of whole grain, whereas masa for Mexican products and chips is whole grain.

In 20 developing countries, primarily in Latin America and Africa, maize gruel is the main food mothers use to wean their babies, and maize is the single largest source of calories. But babies who subsist on maize can face a dangerous lack of protein during a critical stage of physical and mental development. The problem is that diets high in maize lack two essential amino acids needed to prevent malnutrition. Here processing can be important. New varieties have been developed that retain the taste of normal maize, but the nutritive value of their protein is nearly equivalent to cow's milk.

Unusual Grains

Buckwheat is from seeds of a broad-leafed plant rather than a grass. It is popular in Eastern Europe and parts of the former Soviet Union. This whole grain product is sold both raw and toasted and cooked into a pilaf-like dish (called "kasha"). Buckwheat is rich in vitamin B, minerals, and the amino acid lysine. The toasted form is more subject to rancidity. It is processed into "soba" noodles in Japan.

Quinoa has the highest protein content of any cereal grain (20%) and is usually eaten as whole grain. Amaranth is also very high in protein and lysine and offers iron, calcium, and vitamin E.

Conclusions

The role of grains as a source of carbohydrate, energy, dietary fiber, protein, essential fatty acids, vitamin B, and minerals varies depending on the ratio of unrefined and refined grain in the diet, the degree and method of milling and the actual grain used.

Methods that can be employed to improve the nutritive value of cereals include traditional genetic selection, genetic engineering, amino acid and other nutrient fortification, complementation with other proteins (notably legumes), milling, heating, soaking, germination, and fermentation.

The grain which is chosen as the staple, how it is used, what other foods are customarily consumed with it all affect human nutrition. Furthermore within any type of grain, the cultivar or variety can impact nutrition. More research is needed on the effects of

a number of processes on how the macro- and micronutrient and the phytochemical content are altered by processing.

E

ENZYME ACTIVITIES

D J Mares, K Mrva, and G B Fincher, University of Adelaide, Glen Osmond, SA, Australia

Introduction

Enzymes are biological catalysts that direct complex biochemical reactions at temperatures relevant to living organisms and the environments in which they exist. The proteinaceous nature of these molecules allows for a myriad of three-dimensional structures that will accommodate different substrate specificities, and respond to the presence of other "regulatory" molecules, changes in ionic environment, pH, temperature, and hydrophobicity. These interactions often result in alteration to the conformation of the enzyme protein that in turn impacts on binding of substrates, activators, inhibitors, and cofactors, or the efficiency of the catalytic activity. In addition to the mechanisms for controlling enzyme activity, the actual amount of enzyme protein in a cell can be controlled via a balance of synthesis and degradation, thus allowing for many tiers of regulatory control.

Cells in cereal grains contain a multitude of enzymes that are common to all living cells, including animals and microorganisms, albeit with minor variations in structure and specificity depending on the species. These enzymes, which are essential for general cellular metabolism and function, will not be discussed here and the reader is referred to any of the numerous plant biochemistry and general biochemistry texts that are readily available. Rather, this article focuses on some of the enzymes that are critical to the specific functions and structures of cereal grains, or those that influence the end use of cereal grains or the quality of cereal end products. One of the major functions of cereal grains is to synthesize and sequester starch, protein, and lipid in the endosperm tissue, which can subsequently be mobilized in the germinated grain to support growth of the developing seedling. The enzymes involved in the biosynthesis of these stored reserves are discussed in **Lipid Chemistry. Protein Synthesis and Deposition. Starch**: Synthesis. In this article, discussion of enzyme activities in cereal grains will be presented in the context of: synthesis and degradation of endosperm cell walls in relation to the specific functions of this specialized storage tissue; hydrolysis of stored endosperm reserves such as starch during germination and how in barley this has been utilized to advantage in the malting and brewing industries, whilst in wheat the same process presents a challenge to processing if the enzymes involved are synthesized prior to harvest; and finally, enzymes that are synthesized during grain development and retain activity in the mature grain where they influence quality, appearance, or color of end products such as noodles and pasta and storage quality in rice. Brief discussions of enzymes that are active in ripe, quiescent grains, and endogenous enzyme inhibitors will complete the article.

Enzymes Involved in the Synthesis and Degradation of Endosperm and Aleurone Cell Walls

Cell Walls in Cereal Endosperm

Cell walls are central to the growth and development of the endosperm of cereal grains and the remobilization of the stored reserves during germination. They are also important contributors to many quality characteristics of cereal grains. The enzymes responsible for the synthesis and degradation of cell-wall polysaccharides are therefore critical not only to the normal biological functions of the endosperm but also to the subsequent utilization of cereals by humans. The endosperm consists of two distinct tissues, the aleurone and the starchy endosperm, that have different roles. The starchy endosperm forms the bulk of the grain. It is the storage organ for starch, protein, and some lipids, and by the time grains are ripe and ready for harvest, it is a nonliving tissue incapable of synthesizing new enzymes. By contrast, the aleurone is the layer of cells that surrounds the starchy endosperm and responds to signals from the germinating

Table 1 Composition of cell walls in cereal endosperm

Cereal	*Source of walls*	*Major polysaccharides*
Barley	Aleurone	71% arabinoxylan 26% (1,3;1,4)-β-glucan 2% cellulose 2% glucomannan
	Starchy endosperm	75% (1,3;1,4)-β-glucan 20% arabinoxylan 2% cellulose 2% glucomannan
Wheat	Aleurone	65% arabinoxylan 29% (1,3;1,4)-β-glucan 2% glucomannan 2% cellulose
	Starchy endosperm	70% arabinoxylan 20% (1,3;1,4)-β-glucan 7% glucomannan 4% cellulose
Rice	Starchy endosperm	27% arabinoxylan 20% (1,3;1,4)-β-glucan 28% cellulose 3% pectin 15% xyloglucan/mannans

embryo to synthesize and secrete the key hydrolytic enzymes required to initiate degradation of the stored endosperm reserves. The aleurone remains a living tissue throughout development and long periods of storage and also retains some integrity during the early stages of germination to enable the programmed dissolution of the endosperm to proceed. Subtle variations in the fine structures of major wall polysaccharides can have a dramatic effect on the functional and rheological properties of cereal-based products. The major wall components in the endosperm of cereal grains are arabinoxylans and (1,3;1,4)-β-glucans; other wall components include cellulose, protein, other minor polysaccharides, and some phenolic acids, chiefly ferulic acid (Table 1). Endosperm walls generally lack lignin. Although cell-wall components account for only 5–10% by weight of the grain, they can have a disproportionately large impact on grain technology, utilization, and nutrition.

Biosynthesis of Cell-Wall Polysaccharides in Cereals

Given the central role played by cell-wall polysaccharides in cereal processing, there has been considerable interest in the enzymes that mediate their biosynthesis, particularly in the developing grain. Cellularization of the starchy endosperm early in grain development involves "atypical" growth of cell walls around individual nuclei in a multinucleate syncytium. The fertilized endosperm mother cell divides for ~70 h to form up to 2000 free, individual nuclei in the cytoplasm of the central cell. Walls subsequently grow between the free nuclei. After a lag phase, further expansion of the cellular endosperm occurs through meristematic activity of peripheral cells that eventually differentiate to form the aleurone. In barley, the major components of the starchy endosperm walls, (1,3;1,4)-β-glucan and arabinoxylan, accumulate steadily between 13 and ~40 days postanthesis (dpa).

Despite the importance of cell-wall biosynthesis as a determinant of final cereal grain quality, polysaccharide synthases involved in wall synthesis have proved very difficult to purify by conventional biochemical procedures, mainly because they are membrane-bound enzymes and can be rapidly inactivated *in vitro*. A key breakthrough in this area occurred when cellulose synthase genes (*CesA*) were identified in higher plants; subsequently multiple *CesA* genes and multiple groups of cellulose synthase-like (*Csl*) genes have been identified. It is highly likely that the genes encoding (1,3;1,4)-β-glucan synthase and xylan synthase in cereals will be found in the cellulose synthase or cellulose synthase-like gene families, given the structural similarities between cellulose and both the (1,3;1,4)-β-glucans and the xylan backbone of arabinoxylans.

Enzymic Hydrolysis of Wall Polysaccharides in Germinated Grain

Most of the enzymes involved in (1,3;1,4)-β-glucan and arabinoxylan degradation in the endosperm of germinated grain have been characterized in detail, particularly in barley, wheat, and maize. In each case, a battery of hydrolytic enzymes is required to completely depolymerize the polysaccharides. The enzymes responsible are generally synthesized *de novo* in the aleurone layer or the scutellum, and subsequently secreted into the starchy endosperm. Walls of the starchy endosperm are completely degraded during this process, but a thin inner layer of the aleurone cell walls appears to resist degradation, presumably to maintain the structural integrity of the aleurone cells while enzyme secretion is in progress.

The (1,3;1,4)-β-glucans of endosperm cell walls are depolymerized by (1,3;1,4)-β-glucan endohydrolases. The (1,3;1,4)-β-glucan endohydrolases release low-molecular-mass (1,3;1,4)-β-oligoglucoside products that can be further hydrolyzed by exohydrolases such as β-glucan glucohydrolases and β-glucosidases. A second, distinct class of (1,3;1,4)-β-glucan endohydrolase has been described in germinated barley and

in maize coleoptiles. The enzymes release (1,3;1,4)-β-glucans with degrees of polymerization of 60–100, but the enzymes have not been characterized in detail. Their action patterns are consistent with a cellulase, but there remains some doubt as to their precise role in (1,3;1,4)-β-glucan depolymerization in germinated grain.

Arabinoxylan depolymerization in germinated cereal grains also requires the concerted action of a range of different hydrolytic enzymes. (1,4)-β-Xylan endohydrolases hydrolyze glycosidic linkages in the (1,4)-β-xylan backbone of the polysaccharide, and probably require a short, unsubstituted region of the (1,4)-β-xylan chain for activity. Genes and cDNAs encoding barley (1,4)-β-xylan endohydrolases have been isolated, and used to define the expression patterns and chromosome locations of the genes. There is another class of enzymes that can hydrolyze polymeric arabinoxylans from cereal cell walls. These enzymes hydrolytically remove single α-arabinofuranosyl substituents from the (1,4)-β-xylan backbone of the polysaccharide and have been designated arabinoxylan arabinofuranohydrolases. They are probably responsible for the removal of arabinofuranosyl residues prior to (1,4)-β-xylan endohydrolase action in germinated grain, but might also be involved in the modification of arabinoxylan fine structure during wall deposition, maturation, or expansion. Complete depolymerization of oligoarabinoxylosides released from cell-wall arabinoxylans by (1,4)-β-xylan endohydrolase requires the action of α-arabinofuranosidases and β-xylosidases, both of which have been detected in germinated cereal grains.

Role of Enzymes in Malting and Brewing of Barley

Malt is used to give a distinctive flavor and color to a range of foods and beverages and whilst it can be prepared from a range of cereals, barley is the most common starting material. By far, the most widespread use of malt is as a source of fermentable sugars for the manufacture of beer and whisky. Malting equates to germination carried out under controlled conditions that are designed to synchronize the sequence of events and yield a uniform and consistent product. Production of malt has been discussed in detail in **Barley**: Malting, and involves steeping in water, germination or modification, and kilning. Steeping is designed to achieve sufficient grain moisture to initiate processes in the embryonic and aleurone tissues that lead to the synthesis and transport of hydrolytic enzymes into the starchy endosperm. During germination or modification, the cell walls of the starchy endosperm and the protein matrix are degraded, leaving the starch exposed. Finally, the germinated grain must be dried, or "kilned," to reduce moisture to $<5\%$, to stabilize the malt for storage and transport, and to generate a characteristic color, whilst carefully avoiding denaturation of enzymes that will be needed to degrade malt starch to fermentable sugars. In the early stages of the brewing process, the dried malt is milled, "mashed" in hot water for the degradation of starch to sugars, and an extract containing the sugars recovered by filtration.

Enzymes Released from the Aleurone during Modification

Starchy endosperm cell walls are broken down by the combined action of enzymes discussed in the previous section. The keys to this process in barley are the (1,3;1,4)-β-glucan endohydrolases since (1,3;1,4)-β-glucans represent up to 75% of barley endosperm cell walls and there is little or no glucanase activity in ungerminated barley grain. Similarly, disruption of the protein matrix that surrounds starch granules is initiated by endopeptidases (proteinases) that are synthesized *de novo* in the aleurone during germination. This group of enzymes degrades large storage proteins into smaller peptides that are susceptible to attack by exopeptidases, in particular carboxypeptidases, which are already present in the endosperm of ungerminated barley. During modification, as much as 50% of the storage protein may be mobilized. The remaining storage material, starch, is present as highly crystalline granules that can be attacked by α-amylases, albeit very slowly at the temperatures used for germination. This enzyme is also synthesized *de novo* in the aleurone during germination and released into the starchy endosperm. Other enzymes that are present in ripe barley, or are synthesized during germination, and which can impact on malting and brewing include lipases, lipoxygenase, nucleases, peroxidases (PODs), phosphatases, and phytase.

Kilning

During kilning, the "green" malt is dried, whilst ensuring that appropriate enzymes retain activity and desirable flavors and colors develop. Drying is commenced using lower temperatures in order to protect the most heat-sensitive enzymes (glucan hydrolases, endopeptidases, limit dextrinase). As moisture is reduced, these enzymes appear to become more tolerant and temperatures can be increased. By comparison, α-amylase is relatively stable at the temperatures used (up to 75°C) to kiln malt destined for use as a source of fermentable sugars. All enzymes are killed

in the more flavorsome, darker malts used in ale-type beer that are cured at 110°C. Kilning requires careful management, not only to retain the activity of important enzymes but also because these enzymes continue to act on substrates during kilning.

Mashing

This process is an extension of malting during which milled malt is mixed with hot water to facilitate the degradation of starch, in particular, to oligosaccharides and glucose. Starch consists of amylose, linear chains of α-(1,4) glucan, and amylopectin, a highly branched polymer which is composed of linear chains of α-(1,4) glucan are interlinked via α-(1,6) bonds. Starch hydrolysis proceeds very rapidly once the starch, present in cereal endosperm as highly crystalline granules, is solubilized or gelatinized and is initiated by α-amylase which catalyzes the hydrolysis of α-(1,4) linkages in the interior of large starch molecules to release a mixture of small, linear, and larger branched dextrins. Small and linear dextrins are further hydrolyzed by β-amylase (already present in ungerminated barley) and probably α-glucosidases, whilst limit dextrinase hydrolyses the α-(1,6)-linkages in the branched dextrins releasing linear dextrins that can then be broken down by α- and β-amylase. Limit dextrinase is of considerable interest since the branched limit dextrins containing α-(1,4) and α-(1,6)-linkages cannot be fermented by yeast during the brewing process. Synthesis of limit dextrinase lags some days behind synthesis of α-amylase during germination or malting of grains and represents a constraint to rapid and complete conversion of starch to fermentable sugars. This enzyme has consequently become the target of genetic and molecular manipulation in an attempt to further improve malting of barley.

α-Amylases in Developing and Ripe Wheat Grains and their Impact on Processing

Starch constitutes up to 80% of the material in the endosperm of wheat grains and is stored in a highly crystalline form in granules that are laid down during development and ripening. α-Amylase is a critical enzyme in remobilization of the endosperm since it initiates hydrolysis of the starch granules, reducing the large, complex molecules of starch to smaller units as already described. Wheat grain tissues can synthesize two groups of α-amylases, or α-amylase isoenzymes, that differ in genetic control, temporal pattern of synthesis as well as physical and chemical properties. Perhaps the most important group in grains are the high pI group (germination or malt α-amylases) that are products of the α-*Amy1* genes located on the group 6 chromosomes of wheat and that are normally only synthesized in the grains during the early stages of germination. The second group, referred to as low pI (pericarp or "green" α-amylases), are found in the pericarp of immature grains, at low levels in mature grains, and are also synthesized during the later stages of germination. The synthesis of the low pI isoenzymes is controlled by α-*Amy2* genes located on the group 7 chromosomes of wheat. In comparison with other cereal enzymes, the α-amylases are relatively thermostable and remain active at temperatures above 60°C where the starch is gelatinized and becomes extremely sensitive to enzymic hydrolysis.

Under ideal growth conditions, ripe wheat grains contain a small amount of low pI α-amylase and no high pI α-amylase and, following milling, the flour can be used to produce a vast array of processed foods including pan breads, flat breads, noodles, cakes, and biscuits as well as industrial products. For leavened products such as western style pan breads, some α-amylase is required to produce the fermentable sugars needed by the yeast. This α-amylase, often microbial in origin, is normally added in measured amount during mixing particularly in the highly automated bread-making plants that require strict adherence to specifications to maintain quality and efficient production. Under nonideal growing conditions, or as a result of adverse genotype × environment interactions, variable amounts of either, or both, groups of α-amylases may be retained or synthesized prior to harvest and as a consequence the grain may be unsuitable for processing. Wheat with unacceptably high levels of α-amylase is commonly downgraded in quality, often to be restricted to animal feed, and attracts substantial financial dockages. Whilst some of the α-amylase is removed with the bran and germ during milling, at progressively higher levels of activity, more of the enzyme will have been transported into the endosperm and will be recovered in the flour. Excess levels of α-amylase in wheat have a disastrous effect in long fermentation processes, which applies to most types of western style pan breads, and leads to sticky dough that is harder to handle, a sticky crumb, dark-colored crust and loaves with large holes that are difficult to slice and may jam slicing machines. During cooking or baking, the starch becomes increasingly susceptible to attack by α-amylase and even small amounts of enzyme can cause dramatic differences in starch viscosity and product texture. Flat breads, "chapatis," and sourdough breads are more tolerant to α-amylase, whereas Japanese style ("Udon") noodles are very sensitive.

Irrespective of the end product, appearance and quality deteriorate as α-amylase activity increases.

High levels of α-amylase activity in ripe wheat grain can arise via a number of mechanisms. First, the low pI α-amylase that is synthesized in the green (chlorophyllous) pericarp of immature grains may be retained rather than being gradually degraded as the grain matures. This takes place in parallel with the loss of starch granules from the chloroplasts in the immature seedcoat, as the seedcoat tissue desiccates and dies (Figure 1). Frost damage to partially developed grains and conditions of high humidity and low-light intensity during ripening have been associated with this abnormal retention of enzymes. Second, a small number of wheat genotypes have a genetic defect referred to as late-maturity α-amylase (LMA) or prematurity α-amylase (PMAA) that is reflected in the synthesis of high pI α-amylase in the aleurone tissue during the later stages of grain development (Figure 1). This may occur generally or be limited to situations where developing grains experience cool temperatures. LMA, unlike germination or sprouting, is not dependent on rain and does not appear to involve changes in, or signals from, the embryo. Finally, adverse weather conditions (rain accompanied by high humidity) at maturity and prior to harvest may trigger grains to commence germination whilst still in the spike. This phenomenon, known as preharvest sprouting (Figure 2), is relatively common in many parts of the world. The sequence of events that occurs during sprouting follows very closely those observed in isolated grain that is germinated under more controlled conditions. α-Amylase synthesis begins adjacent to the embryo or germ end of the grain and progresses in a wave towards the distal end. The system has been very widely studied by plant biochemists endeavoring to understand the intricacies of control of enzyme synthesis and the role of plant hormones. Initially, only high pI isoenzymes are synthesized, however, as germination progresses the low pI group are also produced. Whilst LMA and sprouting are readily distinguished both in genetic

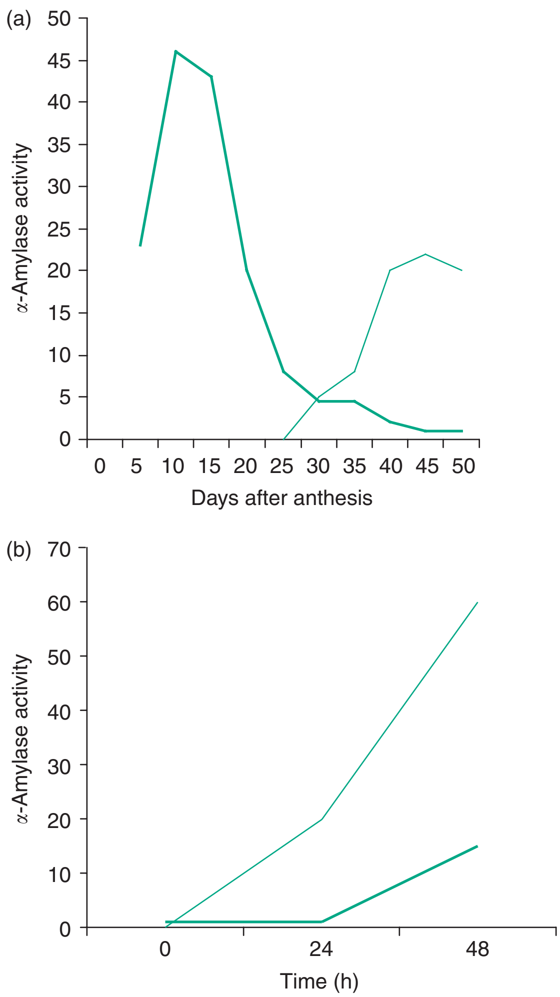

Figure 1 Diagrammatic representation of α-amylase synthesis in wheat grains during development, ripening, and preharvest sprouting. Low pI α-amylase is synthesized in the pericarp during the early stages of grain development, then declines to very low levels at maturity in all genotypes (a), whilst new low pI α-amylase is synthesized by the aleurone later in grain germination or sprouting (b). High pI α-amylase is synthesized in the aleurone during later stages of grain development in LMA-prone cultivars (a) and in the aleurone during the early stages of germination of all cultivars (b). Low pI α-amylase (thick line), high pI α-amylase (thin line).

control and in the pattern of enzyme distribution within the grain, the α-amylase isoenzymes involved are similar, as are the effects on the quality of end products.

Enzymes Involved in Determining the Color and Appearance of Wheat End Products such as Asian Noodles

Large quantities of the wheat used in Southeast Asia, Japan, Korea, and China are consumed as noodles and increasingly these products are also finding a place on tables in western societies. As the markets for noodle products develop and become more quality-sensitive, greater emphasis has been placed on improving appearance, consistency of color, and color stability, because these characteristics strongly influence customer appeal. Asian noodles made from wheat flour come in a wide range of forms, although there are two basic recipes used for production. These are referred to as white salted noodles (WSN), made from flour, water, and varying amounts of salt, and yellow alkaline noodles (YAN), prepared using flour, water, and alkaline salts such as potassium and sodium carbonate. For both types, initial color should be clean and bright and there should be minimal darkening in the time between preparation and cooking. WSN vary from white to cream in color, whilst YAN have a yellow color that is often enhanced with artificial coloring agents or eggs.

Synthesis of Flavonoids and Xanthophylls

The creamy color of WSN and a part of the yellow color of YAN is dependent on natural yellow pigments, xanthophylls (primarily lutein), present in the germ and endosperm of wheat grains. Lutein is a member of the C_{40} terpenoids or carotenoid family of compounds that are found in all plants and are synthesized from isopentenyl phosphate via a biosynthetic pathway commencing with geranylgeranyl pyrophosphate synthase. The additional yellow color that develops in the presence of alkaline salts in YAN is attributed to flavonoid compounds such as flavone glycosides; these are found in the germ and seedcoat but not the endosperm. The starting point for synthesis of flavononoids is phenylalanine and the enzyme phenylalanine ammonia lyase, which leads into a biosynthetic pathway that produces a vast array of structures including flavones, cinnamic acids and lignins, anthocyanins, and tannins. Xanthophylls and flavonoids accumulate during the early to middle stages of grain development, depending on the activity of the enzymes in the respective biosynthetic pathways. In the case of xanthophylls, the levels decline markedly as the grain ripens. Lutein may also be converted to mono- and di-fatty acid esters during storage of ripe grain or flour. Degradation and esterification of lutein are almost certainly controlled by specific enzymes, but these have not been identified. The concentrations of xanthophylls and flavonoids in flour is a product not only of the balance of synthesis and degradation during grain development, but also the milling process, in particular the efficiency of separation of starchy endosperm from other grain tissues such as the germ and seedcoat.

Lipoxygenase

Lipoxygenases (LOX) catalyze the oxidation of polyunsaturated fatty acids such as linoleic and linolenic acid to hydroperoxides. Fatty acid radicals produced during the intermediate steps in the reaction can initiate oxidative degradation of pigments such as lutein and β-carotene. As a result of this co-oxidation, lutein and lutein ester pigments may decline during dough mixing in preparation for production of WSN and durum pasta, leading to poor color stability. Loss of pigment can be reduced by addition of compounds such as α-tocopherol that inhibit LOX activity, or by using durum cultivars that have been selected for zero LOX activity. In addition to its effects on color, LOX has been associated with the formation of compounds with undesirable odors and flavors. Loss of lutein and carotene is also undesirable due to the role these ompounds play in the health of our eyes, in iron uptake in the intestinal tract, and as general scavengers of peroxy-radicals that reduce oxidative damage to tissues.

Polyphenol Oxidase

Polyphenol oxidases (PPO) catalyze the oxidation of phenolic compounds to produce brown pigments on the cut or damaged surfaces of fruits and vegetables, and can cause major economic losses. PPO located in the seedcoat of ripe wheat grains is able to hydroxylate certain phenols in the σ-position adjacent to the existing –OH group to form orthodiphenols. The orthodiphenols are oxidized further by PPO to σ-benzoquinones, which in turn polymerize nonenzymatically to melanins (brown pigments). Fortunately, most of the PPO in wheat grains is removed with the bran during milling, but sufficient enzyme is carried through in the flour of many wheat cultivars to present problems with the color stability of products that are not cooked immediately. Whilst the endogenous substrate of PPO in grains has not been identified, the role of PPO in darkening of WSN, YAN, and durum pasta is now clear. Addition of exogenous substrates such as tyrosine, catechol, and L-DOPA (L-3,4-dihydroxyphenylalanine) enhances noodle

YAN + tyrosine

YAN + tyrosine + tropolone

Figure 3 Noodle sheets prepared with a small amount of tyrosine (polyphenol oxidase substrate) or tyrosine plus tropolone (specific polyphenol oxidase inhibitor) demonstrating the darkening caused by excess amounts of this enzyme.

darkening, whereas darkening is greatly reduced in the presence of specific PPO inhibitors or in cultivars selected for low or zero grain PPO activity (Figure 3). Variation in PPO activity explains most of the genetic difference in noodle darkening between cultivars, but is only responsible for a portion of the total darkening that occurs. Physical effects and other unidentified oxidation reactions also contribute to the reduction in noodle brightness over time.

POD and Hydrogen Peroxide Synthesis and Catalysis

PODs are oxidoreductases widely distributed in higher plants and have been shown to oxidize many compounds, including phenolics, in the presence of hydrogen peroxide. Oxidation of phenolic compounds can lead to the formation of brown pigments similar to those formed by PPO, and consequently PODs have also been implicated in browning or darkening of noodles and pasta. In the case of POD, the situation is complicated by the presence of a number of forms with different substrate specificity that are localized in embryo, endosperm, and seedcoat tissues of wheat grains, and by the interaction of POD with systems that either generate H_2O_2 (superoxide dismutase, NADH oxidation) or catalyze (catalase) its destruction.

In addition to its possible role in product darkening, POD has been implicated in the development of symptoms of a grain quality defect known as “black point.”

Sound grain

Black point

Figure 4 Sound and black point affected wheat grains.

Both wheat and barley are prone to this defect, which manifests as a dark stain in the seedcoat or husk, respectively, at the embryo end of the grain, and is associated with warm, humid conditions during ripening (Figure 4). Unfortunately this pigmented tissue fragments during milling and black specks are carried through into wheat flour or semolina. Whilst it has no effect on processing properties or texture, the specks are visible in noodle and pasta products and high levels of black point result in downgrading and substantial economic losses.

The enzymes discussed in this section all have specific functions within the tissues of developing grains, although in some instances the exact role has not been identified unequivocally. Their physiological functions are quite distinct from their effects on processing and end-product appearance. Whilst in many cases it is possible, or at least conceivable, to develop germplasm with extremes of variability for levels of these enzymes, dramatic changes may have adverse affects on plant growth, disease resistance, or grain yield.

Enzymes that are Active in Ripe, Quiescent Grains

Despite the low-moisture content of ripe cereal grains and the death of the seedcoat and starchy endosperm tissues during grain ripening, it is clear that respiration and some other enzyme-catalyzed reactions continue at a slow rate during storage of harvested grain. Some of these activities result in the modification of the structure of grain constituents and secondary metabolites, whilst others may impact on the storage quality or the capacity to maintain freshness and palatability.

At maturity and depending on the genotype and growing conditions, wheat grains contain varying levels of xanthophyll (hydroxy carotene) present primarily as free lutein. During storage of wheat grain and wheat flour, and again depending on genotype as well as temperature and humidity, considerable proportions of the free lutein (up to 60%) may be converted to mono- and di-fatty acid esters. Fatty acids accumulate as a result of hydrolysis of grain lipids by lipase whilst the enzyme responsible for esterification has not been identified. Interestingly, esterification does not occur in some durum wheat and in a small number of bread wheat cultivars. Since adequate lutein intake is associated with a reduction in the incidence of glaucoma and macular degeneration, a major cause of blindness in elderly people, this modification may have implications for absorption, bioavailability, and attempts to improve eye health through dietary supplementation.

Enzymes have been implicated in the deterioration in quality of rice during storage. This deterioration may be linked to lipid peroxidation, peroxidative changes in polyunsaturated fatty acids that in turn are governed by the balance of production and dissipation of reactive oxygen species. POD is a key scavenger of reactive oxygen species and recent studies have indicated that the activity of this enzyme declines during storage of rice.

Endogenous Enzyme Inhibitors

Cereal and legume grains contain inhibitors against a range of enzymes such as proteinase, α-amylase, endoxylanase, and limit dextrinase. Whilst some inhibitors are only effective against exogenous enzymes of microbial or insect origin, others are capable of inhibiting endogenous grain enzymes. The physiological function of these inhibitors is not certain but it has been suggested that they may be involved in plant defense mechanisms, protecting the stored reserves in the seed from invading microbes and insects, and/or play a regulatory role in plant development and metabolism. A role in the plant defense mechanisms seems plausible given the effectiveness of many endogenous inhibitors against hydrolytic enzymes from microbial and insect sources. Support for a regulatory role is less plausible and requires unequivocal evidence that the inhibitors reduce the activity of particular endogenous grain enzymes at physiological concentrations and that the inhibitors are located in the same tissue as the target enzyme. Most of the proteinase inhibitors that have been characterized to date are inhibitors of a particular class of protein hydrolases, the serine proteinases. As yet there has been no conclusive demonstration of serine proteinases of the chymotrypsin family or their genes in plants. In the case of the bifunctional α-amylase/subtilisin inhibitor (BASI) that is common in barley grains, there is clear evidence that it can significantly reduce the activity of endogenous high pI α-amylase extracted from germinated or malted grain and ameliorate some of the deleterious effects of high α-amylase on loaf volume and structure. However, recent studies of gene expression have indicated that the inhibitor is primarily located in the maternal seedcoat tissues of barley grains rather than endosperm. Similarly, whereas proteins of the "serpin" superfamily are localized in both vegetative and endosperm tissues of barley grains, they only inhibit specific mammalian serine proteinases. Limit dextrinase inhibitors isolated from barley inhibit the activity of endogenous limit dextrinase and appear to be ineffective against a number of other enzymes capable of hydrolyzing α-1,6-linkages in dextrins. In theory at least, these inhibitors could interfere with the malting process although a role in commercial malting has not been demonstrated. Two groups of endoxylanase inhibitors (XIP-type and TAXI-type) have been isolated from cereal grains that are effective against fungal endoxylanases and both bacterial and fungal endoxylanases respectively. Microbial endoxylanases are commonly used in bread making to improve loaf volume.

Irrespective of possible roles in plant defense and regulation, significant numbers of inhibitors are active either against endogenous enzymes that are important in processing or against exogenous enzymes, usually of fungal or bacterial origin, that are added as ingredients to improve processing and quality of end products. In these instances, the inhibitor and the enzyme are brought into contact as a result of milling or deliberate physical admixture and there may be important implications for industrial applications.

Future Prospects

Many cereal products and processes either depend on, or are adversely affected by, specific enzymes that are present in grains at maturity or that develop as the result of interactions between grains and the environment. As more of these enzymes are recognized, and their impact quantified, many opportunities will be presented to improve products and to develop new and novel products and processes. In many cases, there is already sufficient genetic variation within existing germplasm or near relatives for the selection of lines with enzyme levels more appropriate to the particular end-use process, whilst in other instances it may be possible via mutation, genetic engineering, or modification of milling techniques to extend

variation beyond that currently available. Genetic engineering, in particular, opens up the possibility of introducing genes encoding novel enzymes into cereal grains, overexpressing genes controlling synthesis of existing enzymes, or synthesizing enzymes in tissues such as the starchy endosperm where they are currently absent. As an example, identification of the genes should reveal potential strategies for the manipulation of cell wall (1→3,1→4)-β-D-glucan and arabinoxylan levels, for the enhancement of cereal quality and productivity. The three-dimensional structure of one of the barley (1,3;1,4)-β-glucan endohydrolases has been solved and the structural information used to rationally design mutated forms of the enzyme with enhanced thermostability. The increased thermostability of this barley (1,3;1,4)-β-glucan endohydrolase could have commercial potential through its ability to overcome filtration problems and other difficulties encountered in the malting and brewing industries. Increasingly sophisticated and high-throughput genomics technologies, coupled with rapid functional analysis systems, are under development. These new technologies can be confidently expected to identify more genes and reveal potential strategies for further manipulation of enzyme and grain constituent levels relevant to the grains industries in the near future.

EXTRUSION TECHNOLOGIES

R C E Guy, Campden and Chorleywood Food Research Association, Chipping Campden, UK

Introduction

Extrusion cooking technologies for foods and feeds grew out of a process developed by the Adams Company in the 1940s to manufacture snack foods from maize grits. They are derived from the earlier extrusion technologies used to form and extrude sausage meats and pasta. These processes involved conveying, mixing, and compressing of moist materials to form doughs that could be extruded as simple rods, or in the case of pasta, as well-defined shapes.

In extrusion cooking, a feedstock of moist powders is also conveyed, mixed, and compressed before shaping at a die (Figure 1). However, the dough temperature is raised to much higher levels compared to pasta making, in the range from 110–200°C on screws confined within a tubular barrel. This means that any water present is superheated within the dough but remains in the liquid state. The high temperatures also cause changes in the structures and form natural biopolymers, such as starch and soy globulins. Simple physical interactions, such as hydrogen and hydrophobic bonds that hold the subunits together, can be broken at high temperatures and the new forms of the polymer can be released and used to create novel structures for foodstuffs. A particular feature of extrusion cooking is the ability of the processing unit to manipulate these polymers at low moistures and to form doughs or fluid systems from them with the minimum of moisture.

The basis of the technology is the screw system, confined within a barrel that conveys the dough towards small openings at the end of the barrel called dies. In the confined space of the barrel, the dough is compressed and heated to high temperatures, while subjected to high pressures, before being extruded through the dies into the atmosphere. An extrusion cooking process has a number of key features:

- the feeding devices supplying the raw material feedstocks,
- the design of the screw system and its barrel,
- the dimensions and number of the dies, and
- the devices that handle the extrudates.

Extrusion cooking is a continuous process in which the raw material feedstocks are metered into the screws at a constant rate and the machinery maintains a steady state equilibrium. This is achieved by balancing the forward flow produced by the screws against the back pressure caused by the resistance of the dies. It is a multivariate process depending on all the independent variables (those not affected by each other) of the machinery and the raw materials such as the screw speed, feed rate, and barrel temperature of the extruder, and the particle size, hardness, and composition of the raw materials. These variables produce a range of dependent variables (those determined by others) in the barrel, such as the material temperature, the pressure, and the mechanical energy input and a further range of dependent variables in the extrudates and products, such as the size, shape, crumb texture, and moisture levels. The consequence of varying one independent variable may be to change several of the product characteristics. Therefore, a good systems approach must be used to control such a process.

The range of products manufactured by extrusion cooking can be divided into two groups, food and industrial products. In the food sector, there are both animal products and human foods. The animal products themselves, include basic feeds for stock animals, marine feeds for freshwater and saltwater fish, shrimps, or prawns. They also include large markets for both dry and canned dog and cat foods and treats, and a number of products for other pets and for wild and tame birds.

Human foods include the original maize snacks and many new forms including modern versions of prawn crackers, potato chips, tortillas, and other traditional

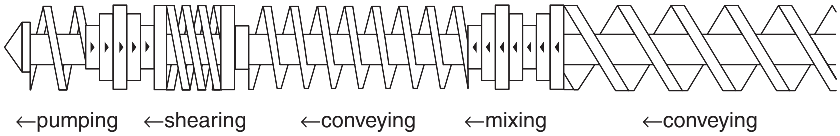

Figure 1 Diagram of the development of raw materials in a twin screw extrusion cooker.

snacks. There are many breakfast cereals products formed in balls, hoops, and flakes from all the major cereal flours and bran-rich recipes, which have large traditional markets in USA and UK and growing markets in many other areas. Similar expanded pieces of rice and maize are used in chocolate confectionery bars. These products called "bullets" of cereal are also used in other products where a crisp expanded foam particle is required, such as museli and granola bars, biscuits, and even in ice cream.

The range of extruded foods has been extended to coatings, such as breadings and flakes. These are used on fried foods, particularly frozen fish and chicken portions. Extruded products have replaced some of the traditional baked crumbs. They are made by expanding cereal extrudates and slicing them into crumbs. This process may be taken a step further in the manufacture of baby foods from extruded feedstocks of cereals and milk powders. For these products, the extrudates are ground to a fine powder, sieved, and used to replace the powders manufactured by the more expensive roller drying process.

Industrial products manufactured from grain include ranges of adhesives or glues and more recently, in biodegradable packaging materials such as expanded loose fill from wheat and maize derivatives and films of polylactic acid derived from maize.

Principles of Extrusion Cooking

Overall Balance of Forces

The extrusion cooking process is used to transform raw material into hot fluid dough and to continue to change the physical nature of this dough until it is forced out of the die. At that stage, the dough must have attained the ideal form to create a structure in the extruded product. This transformation of the native raw materials has an optimum range for most product types. For some products, only small changes in native biopolymers are required, whereas for others a very high degree of change must be achieved. For each individual product type, the process must be maintained in a balance between the independent input variables to obtain the ideal conditions within the barrel to achieve this level of transformation (Figure 2).

A good view of an extrusion cooking process is given by F Meuser and B van Lengerich. They showed that the relationships between the independent process inputs from the machinery and raw materials created a series of dependent variables within the barrel of the extruder. Most notable of these are residence time, temperature, pressure, moisture level, applied mechanical energy, and mass flow rate. Guy and Horne showed that biopolymers in raw materials, such as starch, are affected by these variables so that their physical form changes and dominates the physical characteristics of the fluid dough. As the dough is extruded, the new forms of biopolymers influence the expansion process both in puffing and die swell. Thus, they influence the shape, extent of expansion, and the foam texture of the extrudates.

An important principle that must be understood for this is that the continuous extrusion cooking process is in a metastable steady state. Roberts and Guy showed that all extrusion cooking processes fluctuate as the balance is maintained between the independent inputs of the process. A fluctuation in an independent input that causes a perturbation of the equilibrium balance may either die away or grow and cause a larger fluctuation in the outputs and therefore in the product quality. Therefore, it is important to minimize fluctuations in the input variables, such as powder and liquid feed rates, raw material distribution, and quality.

The Screw Design

The screws of an extrusion cooker are designed to convey a powder or viscous fluid from the feed port to the die and to force the material through the die (Figure 3). Single screws were used in the early machines for production rates of 100–200 $\mathrm{kg\,h^{-1}}$, leading on from the pasta equipment, although twin screws were known and used by sausage makers. More recently, pairs of corotating intermeshing twin

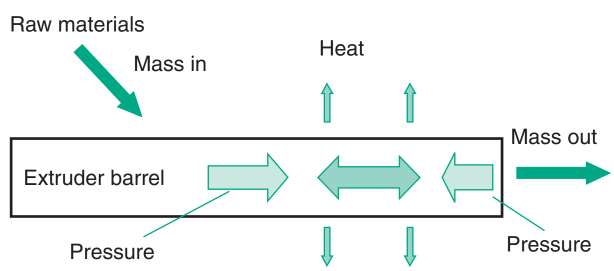

Figure 2 Extrusion cooking showing the balance between mass flow, pressure, and heat flow.

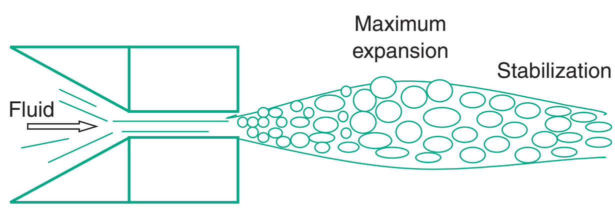

Figure 3 Side view of screw system for a twin screw extruder used at CCFRA showing functions of the elements.

screw machine have been adapted from the plastics industry to become important machines for the food and feed industries. For conveying materials, the screws are designed with a pitch of 0.5–1 times its diameter and a small clearance between the leading edge and the wall. This design will provide a screw with excellent conveying power for viscous fluid and powders. However, its ability to process raw materials is very small.

The second feature for an extrusion cooking screw system is designed to apply high levels of mechanical shear to the feedstock being conveyed along its length. In the single screw, this is achieved by reducing the depth of the flights as the material approaches the die and by introducing cuts in the flights to increase back-leakage.

In twin screw machines, special sections are added in which the flights are reversed to give a backpressure pump acting against the main flow. These sections are made weaker by cutting gaps in the flights, so that the main pumping screws overcome them, thus achieving a steady flow of the powders and melt fluids though the reversing section under shear. In general, the feed material entering the reversing section will be in the form of a moist or dry powder. This will be compressed and heated by mechanical energy plus barrel heating to a high temperature in a short distance. If the temperature is sufficient to melt the crystallites in the raw material it will become soft and form a fluid, otherwise it will remain as a powder and may be extruded without any expansion such as opaque compressed powder from the die. The fluids will lose the air bubbles before reaching the die and become translucent but have the ability to retain bubbles of steam and may expand to develop alveolar structures.

A special form of reverse section can be constructed from elliptical paddles placed on each shaft in a series. If successive pairs are placed at an angle to the upstream pair, a screw-like structure can be formed. This type of section acts on the fluid as it passes through, kneading the fluid against walls and the other elliptical paddles. An important feature of such a section is that it is set up as a reversing screw to ensure that all the paddles are full of fluid. If they are not full, they have little or no shearing effect on the fluid.

The final role of the screws is to push the fluid melt through the dies in a controlled manner. Normally, the extruder is run with the final sections completely full, so that pressure is transmitted from the main conveying screws to the dies. In those cases where reverse sections are used, there may be a pressure drop after the reverse section and a final section of conveying screw can be used to pump the fluid through the die. In most processes, where the extrusion melt fluid has a temperature $>100^\circ C$, the pressure in the die will need to be higher than the water vapor pressure. This will ensure that the fluid emerges from the die and expands in the air rather than in the die cavity. Normally, the pressure at the die for good control of hot melt extrusions will be >40 bar.

The progress in the machinery has been remarkable and the largest machine currently can process $10–30\,t\,h^{-1}$, more than 100 times the rate of the early machines.

The Transformation of Biopolymers

The main feature of extrusion cooking is the transformation of the biopolymers in a raw material feedstock. In 90% of the extruded products manufactured, the active biopolymer is starch, and for the remainder, it is a protein from oilseeds, such as soy, or wheat gluten.

Physical transformation is necessary to obtain a more suitable form of the biopolymer for structure creation in the postextrusion expansion processes (Figure 1).

Starch is found in many of the world major crops, cereals, such as wheat, rice and maize, and in important tubers such as potato and manioc. In all cases, it is found as partially crystalline granules, ranging from 5–100 μm in maximum dimension. The polymers can be released from the granules (Figure 4) either by melting their crystalline regions and applying large shearing forces, or by gelatinizing (melting at 60–75°C and swelling) them in an excess of water ($>30–35\%$). For extrusion cooking at low moistures, 15–20%, the melted starch must be dispersed purely by mechanical shear to obtain a melt fluid of partially, or fully dispersed aggregates. At moistures $>30\%$, the granules swell and are readily dispersed.

The melting temperature for starch granules in a low moisture feedstock may be in the range of 120–160°C. Therefore, it is necessary to heat the feedstock to this temperature by the dissipation of mechanical energy and barrel heating. In systems with $<25\%$ moisture, the action of the screws on the powders being compressed to a density of $1.4\,g\,ml^{-1}$ will normally achieve the required temperature by frictional heating and the dissipation of mechanical energy from the drive motor.

The second part of the transformation of the starch is subtler. It has been shown that the major polymer in starch, amylopectin, is highly branched and has a molecular weight range of $10^8–10^9$ Da. This size range is too large for good flow properties in fluids at the concentrations found in the melt fluids. It interferes with the expansion process and reduces the

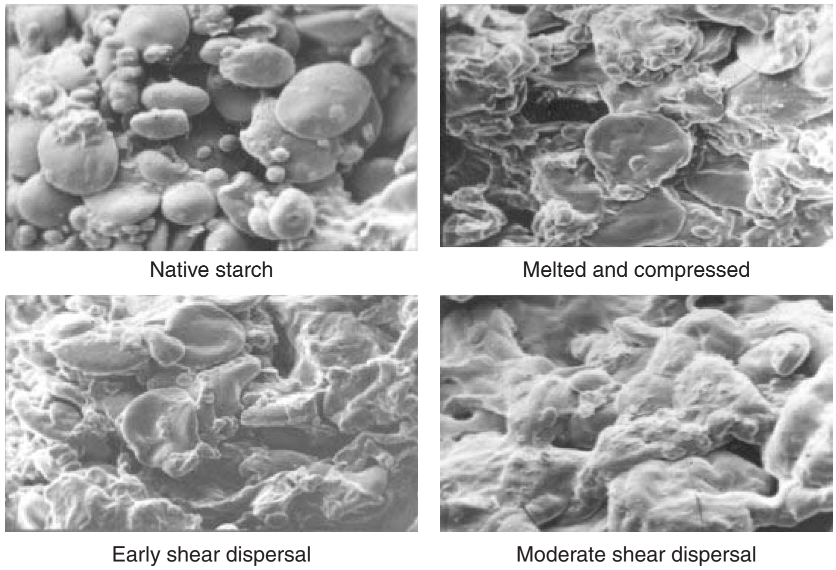

Figure 4 Stages in the transformation of starch in an extruder.

extensibility of the starch films in cell walls. However, the application of high shear inputs to the fluid using reversing screws and high compression ratios can degrade the starch to a much smaller range of $1-5 \times 10^6$ Da. This material is much more extensible and gives a more expanded range of products.

The principle of extrusion is to transform the biopolymers by heat and shearing forces to new forms. This may be a completely dispersed form, in which the native granular structures have all been destroyed leaving the polymers to form a continuous fluid in water. Such processed starch would be suitable for forming films that can retain gases during expansion to form fine foams. In examples with proteins, the polymers may be dispersed in a fluid and then allowed to aggregate during laminar flow through long dies to form sheets or fibers in a texturization process.

The processing of starch may be set up to produce any type of starch structure from the native granules to the fully dispersed and degraded forms. If the range is divided into a number of stages as in Figure 4, the type formed at each stage may be associated with a different product in the list discussed earlier.

Miscellaneous Reactions and Physical Effects

The extrusion cooker is a chemical reactor which can cause interactions between some of the ingredients such as amino acids and reducing sugars to take part in Maillard reactions and similar degradative and condensation reactions. These reactions produce color and flavor compounds and may also reduce amino acid and vitamin contents.

Extrusion cooking also has a unique action which serves to sterilize the materials being processed when their processing temperatures are $>100°C$. The time spent in the extrusion processing zone is short, only 45–120 s in most processes but the high shear fields and temperatures of 140–160°C in the shear zone help to reduce the viable cells and spore counts to low levels. Finally, the explosive release of superheated water from within cells rupture their structure and kills off the remaining viable cells.

Extrusion Cooking Product Technologies

Animal Feedstuffs

The basic stock feeds are made with cookers and pelleting presses operating at $20-50\,\mathrm{t\,h^{-1}}$. This does not gelatinize the starch and merely pasteurizes and compacts the material as loose pellets. The second level of processing is obtained with expanders that add steam to an open screw system feeding pelleting presses. This process also fails to gelatinize more than a small amount of starch, until a die is used and the equipment becomes a full extrusion cooker.

Feedstuffs with gelatinized and dispersed starch are made for special weaning foods and for all the marine feeds for fish and shrimps. In these products, the pellets are held together by the melted dispersed starch so that a strong structure is formed.

Extruders are also used to improve the nutritional value of oilseed and other protein stocks by denaturing proteins, which inhibit digestion such as lectins

and trypsin inhibitors in soybeans and dough ball forming elastic glutenins in wheat flours.

Pet Foods

Dry pet foods are made from an extruded feedstock of cereals, fortified with protein-rich materials such as dried meat meal, chicken digest, and similar materials. They tend to be fairly dense products with a specific density of $0.35-0.45\,\mathrm{g\,ml^{-1}}$. The structural material is normally starch, which is supplied by a cereal such as wheat or maize for standard products, and rice for special dietary feeds. There may also be higher levels of oils and fats and minerals to provide a balanced diet for the animals.

Many processes incorporate a preconditioning unit (Figure 2) in which the bulk of the feedstock is conveyed and mixed with oil and steam to produce a hot feedstock at 80°C for the extruder. This enables a higher throughput of materials to be processed by the extruder.

Processes containing high oil contents must be balanced with materials, which absorb oil and prevent slippage in the machinery. Alternatively, the oil can be sprayed onto the extrudates post extrusion.

Snack Foods

The snack foods are made in several forms by either direct expansion, or by the expansion of dense cooked pellets. In direct expansion, the feedstock may be formed from a cereal or potato base mix containing 75–85% starch. The extrusion process is high shear at low moisture to give highly degraded starch with no granular structure and a large amount of molecular degradation. This allows an expansion to a very low specific density of $0.14-0.20\,\mathrm{g\,ml^{-1}}$. Directly extruded snacks may be formed as tubes at the die and injected with a cream or jam through the center to manufacture a coextrusion or coextruded snack. The simple product is coated with oil and flavorings to complete the process.

For the pellet process, a similar feedstock is processed at low shear to melt the starch crystalline regions but to retain its granular structure. The cooked melted fluid is cooled to 95–100°C after cooking, before extruding as the final shape. This soft dense extrudate is cut into pellets and dried to $<12\%$ moisture. As it cools to ambient temperatures, it becomes a glassy structure and is known as an intermediate pellet or half-product.

A snack is formed by heating the half-product for a few seconds in hot oil or hot air at 190°C. Recent developments have seen the production of such products in two layers with a half-product. On frying, this forms a large central cavity and has been called a 3D snack.

Breakfast Cereals

A simple form of breakfast cereal is made from a cereal feedstock of wheat, maize, or rice flours and some small additions of sugar, salt, and proteins. The feedstock is processed at 20–25% moisture to a medium expansion at 150°C, to give a specific density of $0.22-0.28\,\mathrm{g\,ml^{-1}}$. The desired products are formed with a coarse cellular texture and thick cell walls, so that they remain crisp in milk for a few minutes. This is achieved by melting the starch granules and degrading $\sim$50% of the granular structures.

The recipes for directly expanded breakfast cereals may be varied to form single cereal varieties, such as crisp rice or corn pops, or to form multigrain cereals from blends of wheat, rice, maize, barley, and oats.

A unique form of the expanded breakfast cereal is the high-bran product in which wheat bran may be used at levels of 70–75%. In this product, a small amount of starch (15–20%) is used to bind the bran fibers together in a cellular structure. The starch must be melted and completely dispersed to achieve this effect.

The second major form of extruded breakfast cereal is the flaked product, such as cornflakes or multigrain flake. This product is similar in its processing requirements to the half product snack in that it is made from a cereal feedstock at 120–130°C at low shear. The starch granules are melted, but not dispersed to any significant level. In the process, the cooked cereal feedstock is extruded as a dense fluid at 90°C and cut into small beads. Each bead forms the basis for a flake when rolled out to a thickness of 0.5–0.7 mm. This process occurs under temperature control at 40–60°C and is followed by a toasting process at high temperature of 240°C for a few seconds to blister and dry out the flakes.

The degree of processing of the starch is very important for the quality of the flakes when they are consumed in milk as a breakfast cereal. If the starch is sheared too much, the flakes take up water too quickly and become limp and flabby in the bowl.

Breadings and Coatings

Traditional breadcrumbs are manufactured by making loaves of bread, shredding, and drying their crumb to produce a small range of products. Several extrusion cooking processes have been set up to make similar products from the same materials and a wider range from other ingredients, which cannot be used in traditional bread.

The extrusion of a wheat flour feedstock at 28–35% moisture at temperatures of 110–120°C at low shear produces expanded extrudates with cellular textures similar to breadcrumb. Starch granules within the structure should be melted to lose their crystalline structure, but only dispersed to a small degree to give material for expansion. The extrudates may be cut while still warm and moist to form crumbs, and then dried to <10% to form the glassy structure required for coating crumbs. The recipe for coating crumbs may be based on wheat flour and modified with some chalk to increase the number of cells. Other cereals such as maize and rice may be used with, or instead of, wheat flour to give a variety of products. Maize adds an attractive yellow color to products, while rice gives whiter crumbs.

Baby Food

Extrusion cooking has been used to produce expanded baby foods from rice and vegetable flours such as peas and carrots. These products are similar to snack foods in that the starch must be well dispersed to give good expansion and a light texture. The process must be controlled in terms of temperature to keep the mass temperature as low as possible <130°C during processing. The second form of baby foods is more important because it represents a larger amount of production. It was developed to match the roller-dried instant baby food, which is consumed as porridge, prepared by mixing water or milk with a dry instant powder. The extruded product is made by processing a feedstock of cereals with milk solids under conditions of medium shear input and controlled temperature. The aim is to melt the starch granules, but to retain their structures to a large extent. This gives a high paste viscosity when added to water or milk and produces a more attractive porridge.

It is also important to control the temperature of the fluid to reduce any browning reactions that would discolor the products and reduce the nutritional quality of the proteins.

F

FERMENTATION

Contents

Origins and Applications

B J B Wood, Strathclyde University, Glasgow, UK

Introduction

Fermentations are vital in utilizing many grains, pulses, and other seeds. This article will attempt to place fermentation in context with respect to its contributions to improving palatability, digestibility, and other desirable properties of foods derived from these concentrated, but sometimes, rather uninteresting raw materials. The raw materials from which the foods are derived may also contain toxins or "antinutritional factors" and fermentations can help to ameliorate the effects of these substances on the consumer. Archaeology shows that seeds were used as foods from the very beginning of the transition from hunter–gatherer lifestyles to the more settled communities that were needed to support the greater complexities of even the most primitive agricultural systems. Consideration of how fermentations developed to support consumption of seed-based foods is, necessarily, entirely speculative now.

It is known that the earliest civilizations had well-developed technologies for making staples such as bread and beer, and that they had taken significant steps in selective breeding to effect the transformation of (for example) wild grasses into more productive cereal crops. They surely lacked any conception of scientific breeding, microbiology, or any other, among the scientific disciplines which is in use in modern research, agriculture, and manufacture. A great respect for their powers of observation and *a priori* deduction must therefore be felt, leading to palatable and useful products, and to the start of food industries. Obviously the choice of seeds to use in these ways was heavily influenced by climate and other environmental factors.

Rice, wheat, and rye have become successively dominant crops from South to North in the northern hemisphere. The hardiness of rye and primitive barley strains (such as the bere barley still grown in the Orkney Islands and remote upland regions of Iran) means that these cereals are found in various regions where the environment is too harsh for more tender crops. This article will necessarily rely more on speculation than hard fact, but will make an honest attempt to identify some of the factors underlying the successes of fermentations in processing seed crops.

The Beginnings of Food Fermentation

Although it cannot be known how or when the practice of fermentation in relation to food began, all available evidence suggests that it is a very ancient part of human development. In fact, fermentation can be seen as a subset of biodeterioration. All things that can serve as foods for humans (or any other animal) are, by their capacity to act as foods, more or less unstable. If they are food for mammals, then they will also be able to support the life of many types of bacteria, molds, etc. In practice, even such apparently stable materials as wood are open to attack by microbes, insects, etc. There is a powerful drive throughout nature to use the energy and nutrition present in organic materials, eventually mineralizing these materials back to carbon dioxide, water, and simple mineral salts.

Attacks by such microorganisms are seen as, primarily, a deterioration, or loss of desirable characteristics. Some such changes, however, turn out to have desirable characteristics. Such changes may produce improvements in flavor, odor, and texture. In addition, there is substantial evidence of improvements in nutritional status and value arising from controlled fermentations.

Various studies have shown that even simple fermentations of basic cereal grains with the indigenous (mainly lactic acid bacteria) microflora generate significant increases in the levels of some B-vitamins. There are strong suggestions that plant proteins, which are somewhat difficult for the monogastric digestive system to handle, can be made more digestible through the actions of proteolytic enzymes produced by bacteria and fungi. Many adults are intolerant to lactose, the principal sugar of milk, but fermentations such as those which produce yogurt, reduce or eliminate this problem.

Fermentations can also reduce or remove toxins and other "antinutritional factors." Perhaps the most important example of the former is the detoxification of cassava, while an example of the latter is hydrolysis of phytic acid, with removal of sequestering by it of divalent metals. There is also the prospect that fermentation increases the stability of the affected food, increasing its resistance to attack by other organisms. Before the advent of modern methods for food preservation, such as freezing, canning, etc., even a short extension in storage life would be precious. The prolonged storage possible for the main protein in milk (casein) consequent upon conversion to a hard cheese (such as Cheddar) would thus be of immense value.

It must also be remembered that availability throughout the year is a very modern phenomenon. In any given region (particularly in the temperate parts of the world) food supply is very seasonal. The idea that tomatoes, apples, "new" potatoes, would be always on sale, would have seemed unreasonable even a couple of decades ago. Now it is taken for granted throughout the industrialized world. In contrast to this prevailing situation with respect to foods rendered inherently unstable ("perishable") by virtue of their high water content, seeds were designed by evolution to remain stable and viable until conditions appropriate for germination were encountered. This made them excellent for storage during temperate and high latitude winters and the dry seasons of more tropical climates.

Obviously evolution did not design seeds to be palatable to animals because this would defeat their primary role as reproductive agents. It can be seen in, for example, the evolution of seed-eating birds, a competition between the birds' need to eat, and the seeds' need to survive to germination, and so to resist being eaten. Thus sorghum and millet have bitter-tasting tannins in their outermost layers, and attempts to breed low-tannin cultivars were more beneficial to the birds than to the farmers. Unfortunately, there are no fermentation strategies available at present that can remove such tannins, although it is conceivable that fungal enzymes could be harnessed for this purpose in the future.

On the other hand, antinutritional factors such as trypsin inhibitors are ameliorated by fermentation. Phytic acid presents an interesting situation. It is reasonable to see it as principally a phosphate, reserved for use as required by the developing seedling as germination progresses. However, its capacity to chelate divalent metal ions definitely gives it an antinutritional role, perhaps more particularly for monogastric animals. Also, the lack of phytase in the gastric juices of animals means that its valuable phosphate and inositol are denied to these consumers. Fermentations of "uncooked" seeds permit phytases present in the seed to effect at least a partial hydrolysis of the material, and this may be supplemented by phytases generated by microbes participating in the fermentation.

An Example

The existence of small pits (perhaps a cubic meter, or even less) dug into the chalk of southern England, has long been known, but their purpose(s) remain matters for controversy. One suggestion has been that they would have been used to store grain. However, *a priori* this seems unlikely. In the ground, grain will be exposed to moisture. All seeds will take up available water as a preparation for germination, and will then become more easily attacked by microbes than the dry seeds would be. Chalk, being very porous, will readily conduct water. Thus grain storage in pits dug into the surface of chalk would seem to be an inappropriate method for conserving the material.

However, experiments showed an interesting sequence of events. Dry grain was packed into pits prepared for the purpose, and the pits were then sealed with a cap of clay or other impervious material. Initially, the grain closest to the clay took up water and was then colonized by a range of fungi and other microorganisms. Eventually this agglomeration of grains, hyphae, etc., formed an impervious layer, preventing further ingress of moisture. In addition, respiration by the stored grain and the microbes feasting in the outer layers of the stored material used up the available oxygen, replacing it with carbon dioxide. Thus, at the sacrifice of the outermost layer of the stored material, the bulk of it was preserved for a long time.

This does not correspond with normal ideas of a food-fermentation process. However, it has illustrations for a number of key points. The pit makers could have had no understanding of the processes at work in their pits. Despite this, the prevailing conditions favored growth of microbes in a beneficial way. There was some loss of stored material, but this was an acceptable price for the storage of the rest in useable condition. All of the foregoing is speculation; we can have no certain knowledge of how the pits were used by their makers. The grain storage hypothesis is nevertheless a valid one, and experiments show that the pits would operate as conservation devices.

Historical Background

Very often an understanding of how fermentation began is speculation based on the interpretation of the modern process in the light of the knowledge of conditions in the past. Sometimes this is aided by ancient records, such as pictures from Egyptian tombs or continuing oral traditions, but in many cases such evidence is scanty or entirely absent. Thus, there is a great deal of guesswork in our attempts to reconstruct how particular fermentations originated.

In most cases this is unimportant, but it can be irritating when faced with a product such as "kefir." Here the fermentation relies upon structures called "grains." Modern analyses show that these grains are highly structured arrangements of yeasts and bacteria upon polysaccharide membranes. These organisms can be separately cultivated in the laboratory, but they do not reform into the characteristic kefir grains when cultured together. How did the grains arise? Was this a single event, or did it happen several times (kefir is widespread across Russia and Eastern Europe)? Clearly, it is unlikely ever that the answers to such questions will be known.

Even in simpler cases, such as bread making or the conversion of grapes to wine or grain to beer, there are no records showing the beginnings of such activities. Often there are myths showing such knowledge as gifts from gods or other superior intelligences. Also, foods such as bread and wine frequently have a place in sacramental activities. The giving and consumption of bread and wine, central to the Christian Eucharist, is also found in older traditions, such as those associated with the Roman god Bacchus. This infers the great importance of such activities at the change from hunter–gatherer economies to the beginnings of settled agriculture. The author suggests that this knowledge was an essential part of that change.

The ability to store foods enhanced survival overwinter and in other periods of hardship. Converting dry grains and other seeds into something more appetizing than a gruel must have made agriculture more attractive and valuable. Alcohol, despite its dangers, provided (and still provides), in reasonable moderation, a basis for social interaction. The apparent changes in the nature of consciousness affected by alcohol must have had spiritual significance, and the economic power possessed by those who control its production and distribution remains important to this day.

The vital part played by bread in the agrarian economies of Europe is made starkly plain by the draconian laws controlling the activities of medieval bakers, and that of beer by ordinances such as the German pure beer laws. The trade in fish sauces throughout the Roman Empire affords another example. Fish sauces is often associated with the Far East, but it is known that several fish sauces have been produced in the Mediterranean region since ancient times. Archaeological evidence indicates that these products were traded in substantial amounts throughout the Empire, even as far as Hadrian's Wall. Although it cannot be known for certain their nature, it seems clear that these were important condiments in the Roman kitchen.

The value of vinegar, as both a condiment and a preservative, has been recognized since the most ancient times. It also had importance in medicine and healing. While the earliest vinegars were, as the very name strongly suggests, produced by souring of wine, in more Northern climates, wine was probably too scarce and valuable to be used thus wastefully. Thus vinegars based on malted grains became economically significant. However, to achieve slow acetification, these were still produced by the traditional processes originally developed for wine vinegars (hence the name "Orleans Process" through association with the French town of that name). With the rapid transfer of the British population from a mainly rural existence to an increasingly urban one, consequent upon the Industrial Revolution, the enhanced demand for vinegar resulted in development of the "Quick" vinegar process to replace the slow Orleans method.

Physical and Chemical Properties of Raw Materials for Fermentations

Appropriate fermentation techniques for given products will be strongly influenced by the physical and chemical properties of the raw material(s) to be used in its preparation. It is therefore useful to attempt a classification of raw materials. What follows will be entirely pragmatic, and is not intended as a formal classification scheme. Instead it will be a grouping by the characteristics most relevant to

fermentation procedures. In order to do this, it is first desirable to review the relevant physical and other characteristics.

Of the physical properties, probably the most important will be the availability of water, as this will strongly influence the types of organisms whose growth can be supported on a particular medium, and, in the extreme case, whether any organisms at all will grow on the material in question. Water availability can be limited by simple physical dryness, i.e., the actual absence of water, and by osmotic pressure creating a physiological drought. Salt and/or sugar in foodstuffs most commonly induce the latter. It should be noted that quite low concentrations of salt, well below that which might be expected to induce significant osmotic stress, can strongly influence the course of fermentations. This must have some significance in bread making with yeast, but becomes more significant in certain types of sourdough bread production, for example the German process called the Manheim salt-sour method.

This is a rather simple example of how the chemical composition of the fermentable material is of great importance in determining the types of organisms that can grow on it and the outcomes of fermentations which they affect. In some cases, there will be ample supplies of (for example) sugars to give desired levels of organic acids, B-vitamins to support growth of fastidious lactic acid bacteria, amino acids, etc. In many cases, however, there will be insufficient readily usable material. Then, organisms which can produce and export appropriate hydrolytic enzymes (amylases or proteases, for example) will be at an advantage. They may also prepare the way for later growth of less competent organisms such as yeasts and lactic acid bacteria.

The part played by chemicals in herbs, onions, garlic, etc. can be particularly interesting. These materials are valued principally as flavors in foods, but many of them also have long traditions as healing agents and medicines. There is increasing evidence that these traditions have a secure basis in scientific fact. The review by Sherman and Flaxman discusses claims that onions, garlic, and many culinary herbs are powerfully inhibitory against bacteria associated with food poisoning. Some baked foods use such herbs and spices, but of more evident importance is their role in foods such as continental sausages, where comminuted meat and cereal products are combined with such spices, and some of which use particularly high levels of garlic (e.g., salami). Sausages are harsh environments even without these inhibitors. Yet bacteria such as species of *Carnobacterium* and *Micrococcus* are present in these products, and are thought to be essential for flavor development. How selective is the toxicity of these plant products? There are clearly interesting biochemical challenges here, even if these claims were shown to be fully justified in the field, i.e., in actual food fermentations. It has been pointed out that, for example, salamis, although particularly heavily spiced with garlic, have been associated with serious illnesses due to *Escherichia coli*. Thus, claims of this type need to be assessed very carefully, with purely laboratory studies and robust trials in actual foods being run in partnership with each other, if the effects on food microflora of herbs and spices are to be fully understood.

The foregoing is not intended as a complete discussion of the issues involved here. Rather it is an indication of some of the factors that require consideration when attempting to understand the factors influencing the initial development and subsequent evolution of food fermentations associated with grains and other seeds.

A Classification of Plant Raw Materials

The great diversity of plant materials means that any attempt at grouping into classes will be fraught by difficulties caused by overlaps and ambiguities. For example, tomatoes and cucumbers, although obviously fruit, are often placed among the vegetables, while the edible stems of rhubarb are placed alongside fruits. Thus, what follows is entirely arbitrary, reflecting the practical problems in fermenting plant foods.

Leafy material

Grass and other forage materials are converted into silage on an enormous scale as an essential part of modern ruminant farming. Although not normally thought of as "food" fermentation, i.e., not part of the "human" diet, this is probably the most important among leaf fermentations in the wider context. Among materials for direct human consumption, the best known products are "kimchi" and "sauerkraut." The latter is a highly industrialized process in the major producing nations. Undoubtedly, it was developed principally as a storage process for conserving excess cabbage through the winter in areas where the severe winter weather would destroy cabbage heads left in the fields, while cut heads would quickly deteriorate in store if held as the unmodified material. The key factors for fermentation are provided for by adding $\sim$2–3% by weight of salt to shredded cabbage heads, then packing tightly into containers, where the sap withdrawn from the plant tissue by osmotic action of the dissolving salt quickly displaces remaining air from the plant material. Bacteria naturally present on the plant surfaces drive the lactic fermentation, although there is a tendency towards using selected cultures now. This simple process gave a product

that could be conserved without deterioration for many months, even in the absence of refrigeration.

Obviously, there is no need to continue this process as a means for conserving cabbage in industrialized societies, where advanced storage systems and transportation, which can deliver any food from any part of the world without regard to season, provide complete freedom from the old domination by the solar cycle. However, this has not reduced demand for the fermented product. On the contrary, those accustomed to it have taken its production with them when they have migrated to, and settled in other parts of the world. Consequently its production is, if anything, increasing. The technology is basically the same for the materials discussed in the next section, with the key difference being that they use salt in prepared brine, whereas here dry salt is added to the raw material.

Fruits

Cucumbers are perhaps the classical example here, although olives would be cited first in Mediterranean climates. Other examples include tomatoes. Small onions and certain types of radish roots, although not fruits, are processed in the same way. Again the technology is very simple, easily applicable on a village or domestic level, and originally a way to conserve seasonal surpluses of produce against winter shortages.

Essentially, the prepared material is immersed in a salt solution (brine) and a spontaneous lactic fermentation develops. In reasonably cool conditions, the products are stable during prolonged storage. The observations about the survival of sauerkraut technology, after the conservation need had passed, apply with equal force here, as do those on industrialization of the processes. Olives are remarkable in the market penetration that the fermented product has achieved outside its traditional consumers.

Another type of conservation of fruits relies on fermenting the released juices to produce stable liquids. This is a very pedestrian way to describe the delights of wines and the products from apple (cider; USA "hard cider") and pear (perry) juices, but is deliberately done to place them in a specific context. Undoubtedly, the capacity of the products to induce intoxication would have attracted attention as soon as they were discovered. Indeed, there is ample evidence that birds and mammals are attracted to fermenting fruits, and will manifest clear evidence of drunkenness, and even of addiction to ethanol. In many cases, the intoxication became associated with religious experiences among humans. Despite these complicating sociological factors, alcoholic fermentation can properly be seen as a preservation strategy, essentially indistinguishable from those presented in the preceding two sections.

Sweet fruits have a very short storage life, although strategies have been developed to permit storing some hard fruits (notably apples and pears) for extended periods. At the other extreme, grapes are so easily bruised that picking them for table-use demands great care; the yeasts always present on the grape skins quickly ferment the fruit juice at the slightest opportunity. The only practical alternative to fermentation is drying to raisins, currants, and sultanas.

Roots, Bulbs, and Tubers

In general, root crops are stable enough for their storage in simple systems, and even for them to be left in the ground during winter until required. Thus, with minor exceptions such as the radishes referred to above, root crops are not fermented in temperate climates. Bulbs are also generally stable enough for winter storage, so fermentation in brine is probably done more for culinary than for conservation reasons.

The New World has contributed, among many other valuable crops, three novel starchy crops that have now become so indispensable that their origins now forgotten. Of these, one is a cereal (maize) but the other two are root crops, potatoes (*Solanum tuberosum*) and cassava (*Manioc esculenta*). Of these two, the author has no knowledge of potatoes being fermented, except in the very limited sense of their being a source of starch for alcohol production. Potatoes can produce various toxins as defenses against predators, but protecting the tubers from exposure to light easily prevents production of the most important of these, and the author is not aware of any evidence that fermentations will reduce toxicity of green tubers.

On the other hand, fermentation is absolutely essential for making cassava safe for use. Most varieties are extremely toxic, because of the presence of a cyanogenic glycoside. In the intact tuber this, and the enzyme that can hydrolyze it, are strictly segregated, but mechanical damage brings them into contact, thus releasing the highly toxic hydrogen cyanide. It is clear that even very primitive people from their native habitats had developed techniques for making the tuber comparatively safe to eat. These are not primarily fermentations, depending as they do on the enzymatic action described above to destroy the cyanogenic glycoside. However, the conditions under which the tubers are harvested and prepared for detoxification ensure that there is an abundant microbial flora associated with them.

Lactic acid bacteria, which do not use iron-containing enzymes, are resistant to cyanide, and their growth on the cassava portions produces acidic conditions that both favor the action of the relevant enzyme and help in removal of the cyanide as the unionized

gaseous form. Subsequent processing, such as drying, reduction to granular form and heat treatments such as (in the case of products such as the West African "gari") roasting. Unfortunately, even "garification" will not reliably remove the last traces of cyanide. Although the residual material is below the acutely toxic concentration, it can, by competing with iodide, produce the thyroid gland malfunction known as goiter.

Seeds

The plant products discussed so far have been characterized by high water content. This is true even of the firmest products, such as the root crops. This water content means both that any injury leaves the foodstuff liable to fermentation or other microbial attack, and that even the undamaged item has a restricted storage life because eventually water loss will reduce it to a flaccid and uninviting state. However, some vegetables can be made suitable for storage by deliberate, controlled dehydration.

With seeds, as already noted their evolutionary development resulted in a very dry, tough, long-lasting product. Seeds are also packed with nutrients placed there by the parent plant to support initial growth of the new plant whose embryo the seed contains. Thus a seed has many characteristics, which make it potentially desirable as a human or animal food. From the human viewpoint however, seeds often have significant disadvantages as foods. As harvested, they are difficult to eat. If processed in the obvious way, by soaking and/or boiling in water, the product is apt to be rather bland and unappetizing. Indeed, of the various grains and seeds harvested by humans, only rice is primarily consumed in this way. Comminution by crushing or grinding can effect some improvements, but the resulting gruels or porridges are still of limited appeal. Much the same is true if the material is formed into a paste and baked or roasted.

On the other hand, even the simplest fermentations can effect considerable improvements. For example, a common breakfast dish in Africa is a maize porridge in which the ground maize is left overnight in water, and then boiled next morning, ready for eating. Overnight there is substantial acidification through the action of lactic acid bacteria. Although this is a fairly minor change, the result is a much more appetizing porridge, especially when a little crude sugar is added just before consumption of the cooked material. Most such mixtures of flours and water will develop substantial populations of lactic acid bacteria, alone or associated with yeast cells.

Microbial gas production will cause some expansion of the paste or dough, and give a tastier and more appealing product upon cooking. The most obvious example of this type is of course sourdough bread. It seems reasonable to believe that this is a very ancient product, and archaeological evidence is emerging to support this view. At the most basic level leaving the dough overnight will produce a leavening effect. A simple improvement would be to add a part of a good ferment to a fresh mixture of flour and water. This process, sometimes called "back slopping" remains the basis for much sourdough bread production to the present. Not only does it provide a more reliable fermentation, but also the increased level of microbes present, and the fact that they are already in active fermentation will tend to give enhanced leavening of the bread over that which could be expected from a newly started fermentation.

A more dilute mixture of flour and water would give a crude alcoholic drink. The really important development here was the discovery that germinating the seeds greatly increased the alcoholic content, and the general quality of the resulting drink. Beer production in the West further modifies the properties of the drink by drying and heat treatment of the germinated seeds (barley malt). This also permits production of the malt in quantity greater than is immediately required, and its storage for future use. African sorghum beer does not require this added refinement, and it seems reasonable to think that the earliest barley fermentations would have used "green" (undried) malt. Again the fermentations would have used a mixture of lactic acid bacteria and yeasts. It is clear that from fairly early times residual yeast from beer and wine fermentations were used for bread making. Equally, "kvass" fermentation from rye bread and water uses a portion of sourdough bread ferment to start a new brew going, although once started, it is maintained by "feeding" the ferment with additions of bread and water.

Rice flour mixed with legume seed flour and water will ferment with leavening provided by carbon dioxide generated by heterofermentative lactic acid bacteria. In parts of India, this simple process yields products such as "idli" and "dosa."

It seems that rice will not malt well, although the author is not aware of any specific reason why this should be so. Certainly it is not fermented by processes involving germination. Instead "koji" processes similar to those used for soy sauce and other legume seed fermentations have long been employed in preparatory stages for subsequent conversion of rice into alcoholic beverages, vinegar, etc. Essentially strains of the koji mold *Aspergillus oryzae* producing high levels of amylolytic enzymes are employed to saccharify the rice starch, followed by alcoholic fermentation under conditions such that the fugal enzymes remain active during it, so providing a steady supply of fermentable carbohydrates.

Thus, seeds rich in starch are converted to many foods and drinks by a range of fermentations that depend on yeasts and lactic acid bacteria, alone or in associations. Fermentations of protein-rich seeds, particularly the soybean (*Glycine max*) and the ground nut (peanut, monkey nut, *Arachis hypogea*), of tropical and subtropical origin, together with the seeds of tropical leguminous trees, have provided both staple foods (such as "tempeh" and "oncom" ("ontjom," "onjom," etc.) and flavoring materials (soy sauce, "miso," etc.) throughout the tropics and subtropics for many thousands of years. The driving force for such developments was probably the rather bland nature of the starting materials, but it is now known that fermentations can increase the digestibility of constituents of the seeds, particularly the proteins, enrich the products with extra B-vitamins, decrease concentrations of some toxic or antinutritional factors, and increase the availability of essential mineral nutrients. These fermentations are frequently multistage, using mold fungi to manufacture a range of digestive enzymes, then yeasts and lactic acid bacteria to complete the process. The origins of these fermentations are lost in time, but it is known that soy sauce and miso have existed for at least 3000 years. Legume seeds tend to be rather well supplied with antinutritional factors, and detoxification during the fermentation is a significant benefit of the process. Perhaps the most remarkable example of seed detoxification however, concerns the castor bean (*Ricinus* spp.). This seed contains a wealth of toxic materials, including ricinoleic acid (a powerful purgative), strongly allergenic proteins, ricin, etc. Despite this, in parts of Nigeria the seeds are collected, boiled, de-hulled, wrapped in leaves and allowed to ferment, then used as a food flavoring, apparently without any ill effects on its consumers.

Types of Fermentations

It is worth noting the range of fermentation procedures developed for dealing with foods. The simplest are probably the liquid fermentations used in making drinks such as beers, kvass, wines, and some of the milk products such as yogurt and buttermilk. These are sometimes called suspension cultures because the microbial cells float suspended in the surrounding liquid. Another name is stirred tank reactor fermentations. Fermentations involving molds usually require free access to the air, both to meet the organism's need for abundant oxygen, and to remove the products of the fermentation, principally carbon dioxide and heat. In one case (tempeh), however the process requires a very limited exposure to oxygen, traditionally achieved by wrapping the substrate in banana or teak leaves, although plastic bags pierced with a pattern of fine holes now often replace these. Such fermentations, which do not require free liquid water, are described as solid substrate processes. Some lactic fermentations, for example, of starchy or farinaceous materials, might also be placed here, as might sausage fermentations. When a solid substrate is in free water, it appears that this is just a type of suspension culture, but there is evidence to suggest that the active microbes attach themselves to the solid material to a considerable extent, thus producing some characteristics of a solid substrate process. The kefir grain provides an interesting problem. Attachment of the cells to the polysaccharide membrane suggests solid substrate process, but analysis of the fermentation shows that there are large numbers of cells suspended in the liquid, quite free of the grains, and that the proportions of bacterial species in suspension are radically different from the proportions within the grains. In Orleans vinegar production, the acetification is effected by a layer of bacterial cells growing as a film or skin at the interface between water and air, so exhibiting some characteristics of a solid substrate process. The "Quick" process features a layer of cells on the surface of the wood shavings, irrigated by the recycling liquid, but also supplied with abundant oxygen, thus showing an even closer relationship to solid substrate process. Citric acid production by *Aspergillus* used to require static growth on the surface of a liquid layer, rather like the Orleans vinegar process. Some processes were described using growth on bamboo supports and a liquid recycle like the "Quick" vinegar process, but it is not clear if these were applied on a production scale.

The Future for Traditional Fermentation Processes

Some very ancient fermentation processes continue to flourish and develop on a very large scale. Soy-sauce production almost seems capable of expansion without limit, as does cheese. Yogurt has been a remarkable success story, with market penetration far beyond its traditional homelands. Vegetable fermentations, such as sauerkraut and olives also seem to grow, although they perhaps do so more slowly than some of the other cases cited. The sourdough bread story is another remarkable one, with the product now on offer at (it seems) every airport in the USA. There does not seem to be any fear for the future of these and a selection of other products. It is also noteworthy that cereal-based products, notably bread and beer, are effectively penetrating markets (such as South-east Asia) where they did not have a traditional role before colonial times.

On the other hand, there is substantial concern for some of the more modest traditional fermentation processes found in the developing countries. These have made a significant contribution to the peoples' nutrition in the past, and the example of tempeh shows how they can substantially improve the nutritional status of the poorest folk. Tempeh itself seems to be robustly addressing the challenge offered by modernizing Indonesian society, but this is an exception. Sorghum beer in South Africa is another example where (in this case with intelligent support from the central government) a traditional food item continues to enjoy a place in an evolving society's markets. In many cases, however, modernization tends to displace traditional foods with imported ones perceived as more "Western" by precisely those consumers who are least able to afford the change to imported food fashions. The drift from rural to semiurban living exacerbates the situation. The traditional food fermentation processes are essentially rural, low technology processes conducted at an almost domestic level. Hygiene considerations alarm the Western observer, but in general the adapted consumer population seem to suffer no harm from these products. There are exceptions of course. The continuation of poisoning outbreaks caused by consumption of "tempeh bonkrek" in Indonesia, despite the authorities' efforts to ban its production, demonstrate the kind of danger which exists. On balance, however, the author's opinion is that loss of traditional knowledge regarding the conduct and management of traditional fermentations will be a serious matter. This knowledge tends to be the preserve of women. Young people are not interested in learning about these matters, and emerging societies tend to place an even lower value on "women's knowledge" than developing ones do. Courses on food, fermentation, etc., need to place stress on the value of such information. This is perhaps the only way in which this unique knowledge pool can hopefully be conserved.

Foods and Nonalcoholic Beverages

J R N Taylor, University of Pretoria, Pretoria, South Africa

Introduction

Fermented foods (including beverages) can be defined as "food substrates that are invaded or overgrown by edible microorganisms, whose enzymes and metabolic processes modify the substrate producing nontoxic flavors, aromas, and textures attractive to the human consumer." As grains are the world's most important foodstuffs there are several categories of fermented grain foods and beverages. This article, however, will only deal with cereal-based products that are produced with a predominantly lactic acid bacterial fermentation. For others, such as: mold fermentations of vegetable meat substitutes, *see* **Beverages**: Distilled. **Soybean**: Soy-Based Fermented Foods; **Soymilk, Tofu, and Okara**; and for yeast leavened breads, *see* **Breads**.

This article will examine the lactic acid bacteria responsible for lactic acid fermentation and the fermentation process itself, the safety and nutritional aspects of lactic acid fermented cereal foods and nonalcoholic beverages (LAFCFANAB), the different types of traditional LAFCFANAB, production processes for specific examples where commercialization has already taken or could easily take place, and lastly the potential for further development of LAFCFANAB.

Lactic Acid Bacteria

Lactic acid fermentation is carried out by several different genera of bacteria, collectively referred to as lactic acid bacteria (LAB). They are with some exceptions, gram-positive, catalase-negative, nonspore-forming spheres and rods. Currently the LAB group comprises 11 genera: *Carnobacterium*, *Enterococcus*, *Lactococcus*, *Lactobacillus*, *Lactosphaera*, *Leuconostoc*, *Oenococcus*, *Pediococcus*, *Streptococcus*, *Vagococcus*, and *Weissella*. The *Lactobacilli* are probably the most important in LAFCFANAB. LAB can carry out respiration without oxygen. Carbohydrates such as glucose are partially oxidized with the release of energy in the absence of any external electron acceptors. The final electron acceptors are organic compounds, specifically lactic acid, produced directly from the breakdown of the carbohydrate. Although the process releases much less energy than aerobic respiration, it confers considerable competitive advantage to the LAB in that an anaerobic, low pH environment is created in which LAB can flourish.

LAB can be conveniently divided into two groups: homofermentative and heterofermentative. Homofermentative types produce lactic acid as the major or sole product of glucose fermentation, whereas the heterofermentative types produce equal molar amounts of lactic acid, carbon dioxide, and ethanol. Heterofermentative types also produce more of the generally desirable flavor compounds such as acetaldehyde and diacetyl. The genera *Pediococcus*, *Streptococcus*, *Lactococcus*, and *Vagococcus* are all exclusively homofermentative, whereas the important *Lactobacillus* genus comprises homofermentative and heterofermentative species. The other LAB genera are all heterofermentative.

Factors Affecting Fermentation

Most LAFCFANAB are produced using a natural, mixed microbial culture. The original source of microorganisms is the environment and the cereal food or beverage itself. Some products are produced with a so-called "spontaneous fermentation" where the product or intermediate is simply incubated at a suitable temperature for up to 72 h. However, in most cases a culture is maintained and optimized by the process known as "back-slopping." A portion of the food/beverage or intermediate that has undergone a successful fermentation is kept back and used to inoculate a new batch. Although apparently crude, back-slopping is highly effective. This is because the environmental conditions of the fermentation favor the growth of the desired bacteria strains.

Several intrinsic and extrinsic factors affect the intensity and particular type of fermentation. Intrinsic factors include the pH, moisture, redox potential, and nutrient content and composition of the food or beverage. For example, yeasts grow over a wide pH range, although a pH 4–4.5 is favored, whereas LAB will grow at low pH ($<$pH 4) and through the production of lactic acid, the pH can be lowered further. In contrast, most bacteria, especially many spoilage bacteria and all pathogenic bacteria, do not grow at such a low pH. This has important consequences with regard to the shelf life and safety of LAFCFANAB. Moisture, or more strictly water activity (a_w), which is an expression of water availability in the food system, controls the rate of microbial growth. Most bacteria require a minimum a_w of 0.9 for growth, whereas yeasts have a somewhat lower minimum a_w 0.88. Microorganisms are sensitive to redox potential (Eh). Aerobic microorganisms require positive Eh for growth, whereas anaerobes require negative values. The presence of, for example, reducing sugars such as glucose maintain the reducing conditions required for the growth of anaerobes. Oxygen itself also plays an important role in determining the nature of the fermentation. The anaerobic environment, in which LAB will grow, prevents the growth of obligate aerobes.

The nutrient content and composition of the food influences the particular type of fermentation. Despite the fact that mixed cultures are used to produce these fermented products, there is generally a clear distinction between those that are alcoholic and those that are sour and substantially nonalcoholic. This is primarily as a result of the fact that yeasts tolerate much higher levels of sugars than bacteria. Hence, under high sugar conditions, alcoholic fermentation is favored.

External factors, particularly temperature, also have an influence. The LAB fermenting cereals tend to grow best between 20°C and 32°C. At such temperatures, the fermentations are invariably heterofermentative. However, a few species, notably *Lactobacillus leichmannii* (*delbrueckii*) which is homofermentative, will grow at much higher temperature, 48–50°C.

These various factors, particularly in traditional fermented products where spontaneous fermentation or

back-slopping are relied upon, generally result in a sequence of different organisms responsible for the fermentation. Many lactic acid fermentations are initiated by spherical bacteria such as *Leuconostoc mesenteroides* and *Pediococcus*. The rod-shaped bacteria such as *Lactobacillus plantarum* and *L. brevis* then take over and lower the pH to ~3.6. Alternatively, a yeast alcoholic fermentation may initiate or follow the LAB fermentation. The complexity of such systems, especially as conditions invariably vary between producers and even between batches, poses great challenges to the food microbiologist attempting to elucidate the microorganism(s) of importance in a particular product.

Food Safety and Nutritional Implications

People worldwide enjoy the sour, sharp, refreshing taste of lactic acid in foods, not just in cereal foods, but in vegetables such as sauerkraut and dairy products like yogurt. In addition, the lactic acid fermentation has effects on the food that are perhaps more important than sensory.

Food Safety

LAB fermentation of porridge to a pH of 4.0 or below will inhibit the growth of Enterobacteriaceae, including pathogenic bacteria such as *Salmonella typhimurium*. It appears that the growth of gram-negative intestinal pathogenic bacteria such as enterotoxigenic *Escherichia coli*, *Campylobacter jejuni*, *Shigella flexneria*, and *S. typhimurium* is strongly inhibited by the low pH caused by the formation of lactic and acetic acids. In slight contrast, the inhibition of the gram-positive *Staphylococcus aureus* is possibly also due to the formation of bacteriocins, antibiotics produced by the LAB. The inhibition of food-borne pathogens by LAB fermentation is of great benefit in developing countries, where even today many people do not have access to safe water. The implications of this are profound. The World Health Organization (WHO) estimates that annually there are ~1500 million episodes of diarrhea in children under the age of five and over 3 million children die as a direct result. In many areas of the world, cereal gruels and porridges are generally used as weaning food for infants. Hence, the WHO is promoting lactic acid fermentation, together with hygienic food preparation practices, as a way of helping to ensure the safety of food.

It has also been reported that LAB fermentation of aflatoxin-contaminated maize or sorghum to produce porridge, reduces the level of aflatoxin by more than 70%. Notwithstanding this apparent benefit, the preparation of food from mycotoxin-contaminated grain is not a practice that should be encouraged.

A further real advantage of LAB fermentation is that the low pH slows down the rate of microbial spoilage of the foodstuff due to other bacteria. The growth of spoilage bacteria is inhibited by the environmental conditions created by the LAB. Hence, LAB fermentation can be considered as a way of extending the safe storage life of foods and beverages. This is of particular importance in the less-developed world where the vast majority of households do not have refrigerators.

Nutritional Implications

There is evidence that LAB fermentation can reduce the viscosity of porridges. The extent of viscosity reduction is affected by factors such as the pH attained and whether the organisms involved possess amylase activity to hydrolyze the cereal starch into dextrins and sugars. Viscosity reduction is greatly enhanced if fermentation is combined with the addition of malted (sprouted) cereal flour that contains high levels of amylase enzymes. Viscosity reduction is especially important in cereal weaning porridges for infants. Porridges where the starch is unmodified can have very high viscosity making them unpalatable. If they are diluted to reduce viscosity, there is a concomitant reduction in energy and nutrient density. Reduction in viscosity with fermentation and malt addition, as is done in the porridge "togwa" from Tanzania, can improve palatability and enable a porridge of higher energy and nutrient density to be produced without it having excessive viscosity.

LAB fermentation has also been found to increase *in vitro* carbohydrate availability. Although the quantity of protein present in cereals is little affected by fermentation (Table 1), the quality in terms of both lysine availability and relative nutritional value is in general significantly improved. These improvements are probably brought about by a combination of the low pH and bacterial proteolytic action, which modifies the structure of the cereal proteins. In sorghum, where cooking to make the porridge reduces protein digestibility, fermentation appears to counteract this effect, improving *in vitro* protein digestibility.

With regard to micronutrients, there is some indication that B-vitamins, particularly thiamine are increased in LAB fermentations. However, the findings are not clear-cut, presumably because of differences in the extent and type of fermentation. The quantity of minerals in cereals cannot be affected by LAB fermentation. However, there could be some improvement in their availability since the quantity of phytate (myo inositol hexaphosphate), a powerful chelator of divalent metal ions such as calcium, magnesium, and iron

Table 1 Effect of spontaneous fermentation for 6 days[a] on the protein content, available lysine and relative nutritive value of various cereals

which occurs in grains, is substantially reduced by fermentation.

LAB fermentation may have negative nutritional effects. Some lactic acid bacteria, generally mesophiles (bacteria which grow at ambient temperatures), which are the norm in traditional fermentations, produce both optical isomers of lactic acid: L(+) and D(−). Since the latter cannot be metabolized by humans, excessive intake may result in acidosis, a disturbance of the acid–alkali balance in the blood. WHO recommends that young babies should not be fed with foods containing DL or D-lactate.

Types of LAFCFANAB

LAFCFANAB can be categorized into flour/meal, pancakes, doughs/dumplings, cakes/sweetmeats, thick porridges, thin porridges, and beverages (Table 2). This classification is inevitably arbitrary. For example, the difference between thick and thin porridges, and between thin porridges and beverages is often simply an issue of how much water is in them, which may be a matter of personal taste. Other products such as "koko," "ogi," and "pozol" are prepared as a dough but consumed as thin porridge or beverages. Another dough product "mawe" is even consumed in a wide variety of including dumplings, steamed bread, fritters, couscous, and thick porridges.

It can be seen from Table 2 that LAFCFANAB are widely distributed throughout the world, occurring in south-east Europe, right across Asia especially in the Indian subcontinent, throughout Africa, and in northern Latin America. The list is by no means complete and the impression given that the largest number of such products occurs in Africa may not be entirely correct. However, it is probably significant that there are many LAFCFANAB in Africa. Africa is the only continent that straddles both tropics and the warm ambient temperature, facilitates the natural proliferation of lactic acid bacteria in foods left to stand, as for example mesophilic *Lactobacilli* have a temperature optimum in the range 28–32°C.

An example from each of the LAFCFANAB categories will now be examined.

Flour/Meal

In northern Namibia, pearl millet is the staple and is generally eaten in the form of porridge. The traditional process of milling pearl millet involves a steeping (fermented) step. Since the country's independence in 1990, fermented pearl millet flour ("uusila" or "oufila") has started to be produced commercially in small mills as a convenience product (Figure 1a), particularly for urban dwellers and institutional feeding. The flour is also used to make a beverage ("oshikundu"), porridges, cakes, and cookies.

The steeping (fermenting) vessels and drying floor of a pearl millet mill in northern Namibia are shown in Figures 1b and 1c, respectively. The process is described in detail in **Millet**: Pearl. In brief, it involves abrasively de-hulling the grain, then steeping it overnight. The steep is also a lactic acid fermentation with a culture being maintained by back-slopping. The bacteria responsible are not known, but are probably heterofermentative *Lactobacilli*. The steeped grain is partially dried in the sun, then hammer-milled into a flour and then fully sun-dried. The fermented flour has a pH between 4 and 5, and a slight acidic taste, which is favored by consumers. The lactic acid fermentation has a number of other positive effects. It lightens and brightens the flour as a result of the low pH

decreasing the color of the pearl millet polyphenolic pigments and also leaching some out. The fermentation also facilitates the grain being reduced into a soft flour (particle size $<500\,\mu m$) during milling, which enables baked goods of reasonable quality to be produced from it, despite the fact that pearl millet does not contain gluten.

Pancakes

"Injera," a large (50 cm diameter) leavened pancake is a staple food of Ethiopia. Injera is sour in taste, flexible and spongy in texture with a characteristic honeycomb-like structure (Figure 2a). It is served at most meals, generally with a spicy meaty relish. Injera is almost exclusively home-produced and is preferably made from teff and/or sorghum flour, although flour of other cereals may also be added. Injera is thus rather unusual in that it is a leavened bread-like product made from nongluten containing cereals.

The process for making injera is described in detail in **Teff**. In brief, it involves two fermentations. In the first, a starter culture ("irsho") from a previous injera batter is added to the flour dough. The fermentation takes up to 72 h, during which time the pH falls to ~pH 3.8. A portion of the dough, ~20%, is then diluted with water and cooked to gelatinize the starch. This product is called "absit." The absit is then combined with the fermenting dough and a second fermentation of ~2 h takes place, during which time gas is generated. The dough is thinned to a batter and then poured in a circular motion over a hot clay griddle ("mitad") (Figure 2b). The "injera" is then covered and baked and steamed for 2–3 min. During this time, the starch gelatinizes setting the batter, and gas bubbles expand and escape creating the honeycomb-like structure.

(a) (b)

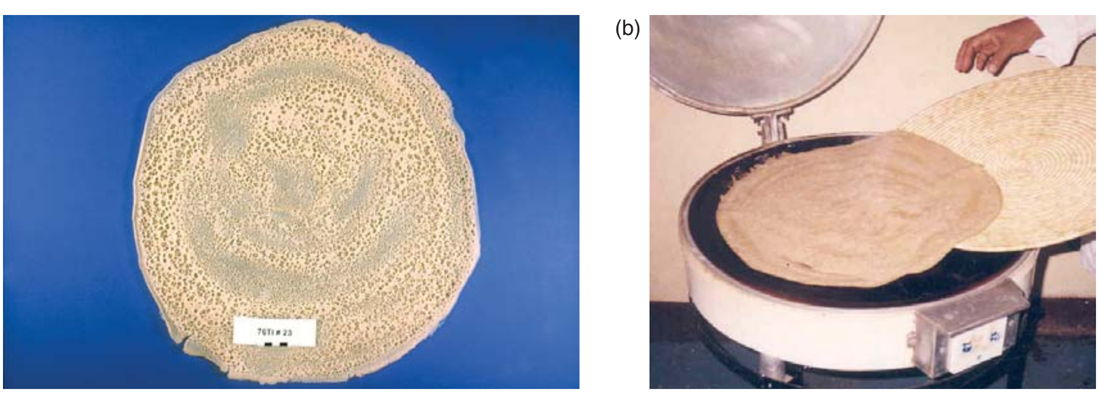

Figure 2 Injera: (a) sorghum injera showing honeycomb-like structure and (b) removing from the clay griddle (mitad).

The microbiology of the injera fermentations is complex. The first fermentation is believed to be initiated by Enterobacteriaceae, then LAB including *Leuconostoc mesenteroides*, *Streptococcus faecalis*, *Pediococcus cerevisiae*, *Lactobacillus brevis*, *L. plantarum*, and *L. fermentum* are involved. Yeasts of the genera *Saccharomyces* and *Torulopsis* are involved in the second fermentation that produces the leavening gas.

Cakes

"Idli" is a small fermented and steamed cake with a characteristic sour taste and leavened texture, made from rice and black gram. It is widely consumed in southern India and Sri Lanka, where it is a breakfast food. Idli is consumed with chutney, pickles or curry. The combination of a legume and a cereal makes idli highly nutritious with a good essential amino acid balance. As can be seen, the idli making process (Figure 3) has some similarities with that of injera. However, for idli it is known that the main fermentation organism is *Leuconostoc mesenteroides*. This heterofermentative bacterium produces both lactic acid and carbon dioxide. During fermentation the pH of the batter decreases from pH 6.0 to 4.3 and the volume increases by 1.6–3.1 times. It is believed that mucilaginous polysaccharides and globulin proteins from the black gram stabilize a gas-holding foam. This enables the formation of a leavened cake. Other bacteria found in the idli fermentation include: *Lactobacillus delbrueckii*, *L. fermentum*, *L. lactis*, *S. faecalis*, and *P. cerevisiae*. Several types of yeasts have also been implicated in the fermentation including species of *Geotrichum* and *Torulopsis*.

As an alternative to steaming, the thick fermented batter can be diluted to a thin batter and seasoned and then fried to produce a pancake called "dosa."

Dumplings

"Kenkey," a staple food in Ghana, is an orange-sized dumpling produced from fermented white maize with a solids content of ~35%. It is produced in the home and by street vendors. Kenkey is eaten at main meals, served with a relish often made with oily fish such as herring.

It can be seen that there are in fact two fermentations in kenkey making, the first while steeping the whole maize and the second a fermentation of the dough (Figure 4). After the second fermentation, the pH should be ~pH 4. The main LAB found in the fermenting dough are *Lactobacillus plantarum*, *L. confusus*, *L. brevis*, and *Pediococcus pentosaceus*. As the pH decreases and titratable acidity increases the heterofermentative types are succeeded by the more acid-tolerant homofermenters.

As in injera making, part of the dough is cooked to gelatinize the starch and hence bind the dough into a cohesive mass. However, in kenkey this dough is not

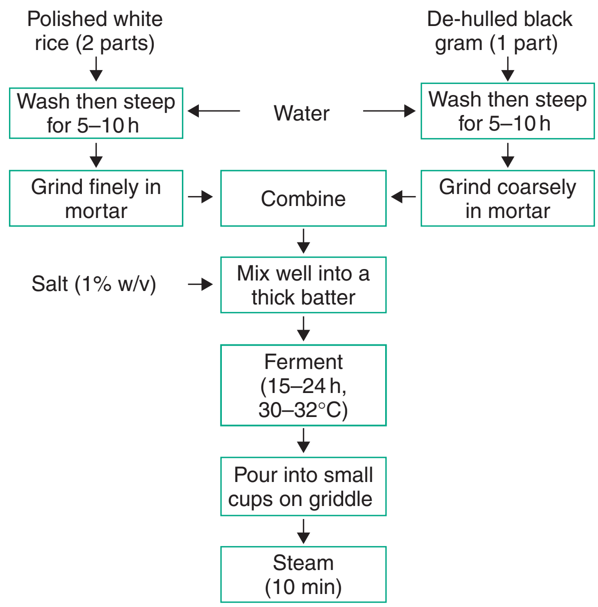

Figure 3 Process for making idli.

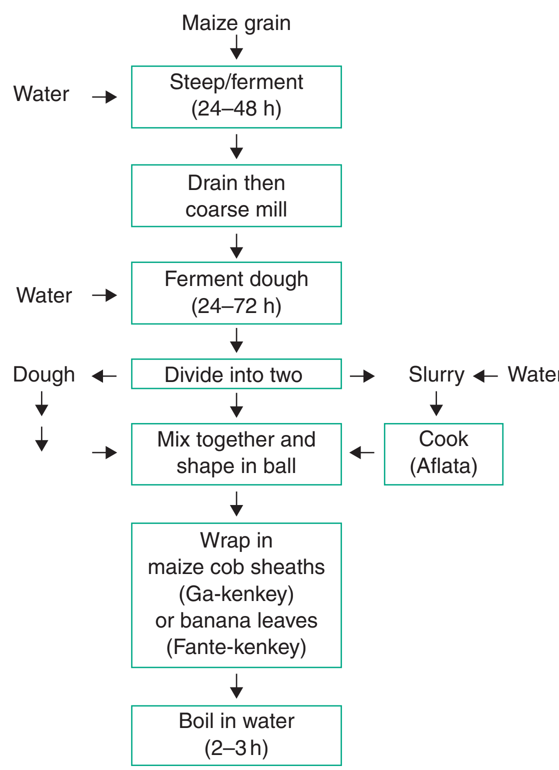

Figure 4 Process for making kenkey.

(a) (b)

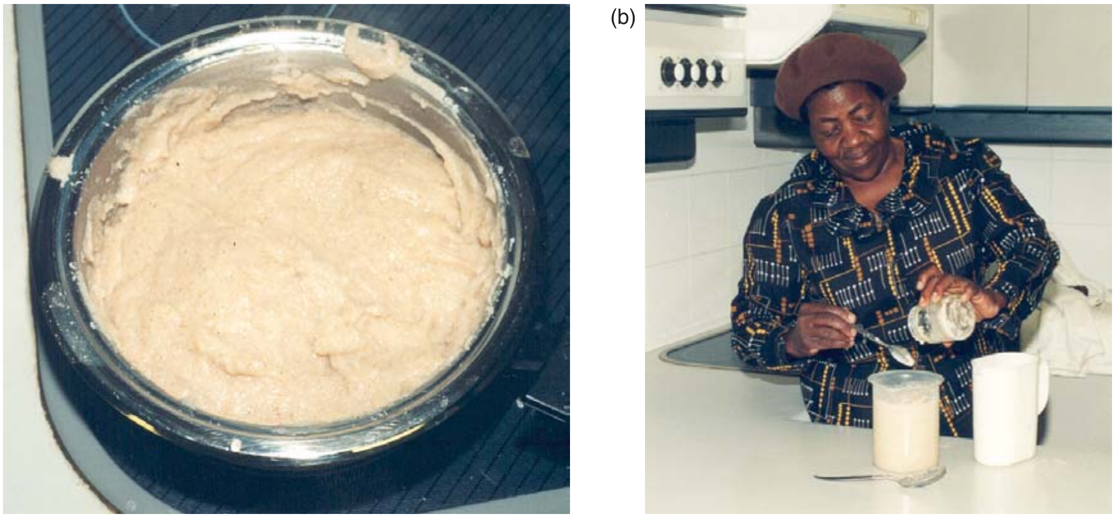

Figure 5 Ting: (a) cooked ting showing its firm consistency and (b) maintaining the culture (letlhabego) by back-slopping.

leavened by a subsequent fermentation, but simply cooked in water.

Research has been undertaken to simplify the kenkey making process for potential industrial manufacture. Developments include accelerating the fermentation process by using a starter culture, and producing dried fermented flour (like the pearl millet flour) and pregelatinized fermented flour.

Thick Porridges

"Ting" is a firm, fermented sorghum porridge with a solids content of ~15% and pH in the range 3.6–4.3 (Figure 5a). It is widely produced in the home in Botswana and northern South Africa. Ting is eaten as breakfast porridge and is often served at celebratory functions.

In South Africa, ting is generally produced from coarse sorghum meal, industrially manufactured for the purpose from red, condensed tannin-free sorghum. In Botswana, meal from white sorghum is generally preferred, which may be produced industrially or by small village mills. A ting-making process used in South Africa is shown in Figure 6. To start the process from scratch, a spontaneous fermentation is carried out at room temperature. The meal sours rapidly with some gas production. The fermented meal, called "pediso," can be used to inoculate more sorghum meal to produce a culture known as "letlhabego" or directly to make ting. Many households maintain a letlhabego, also known as a "yeast," by back-slopping, the use of which shortens the process of ting making (Figure 5b). As the letlhabego is so useful, it is also traded in townships. The LAB *Lactobacillus delbrueckii*, *L. curvatus*, and *Leuconostoc mesenteroides* have been found to be the predominant species

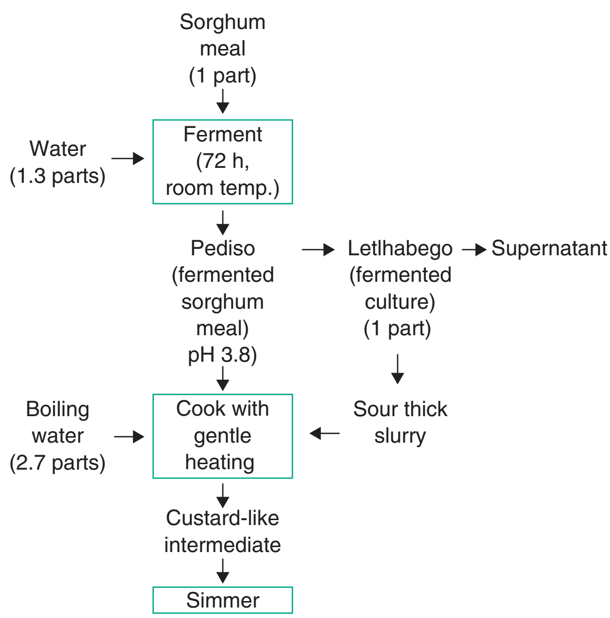

Figure 6 Process for making ting.

in the *letlhabego*. To prepare ting, the pediso or letlhabego is added to boiling water and cooked as shown. In South Africa, industrially produced ting made from maize and sorghum has been developed. It is marketed in polythene sachets and has a shelf life of several weeks, due to its low pH. The product, however, has not been commercially successful on account of its high price.

Thin Porridges

"Ogi" (north west Nigeria) or "akamu" (eastern Nigeria) is a thin, sour porridge of solids content

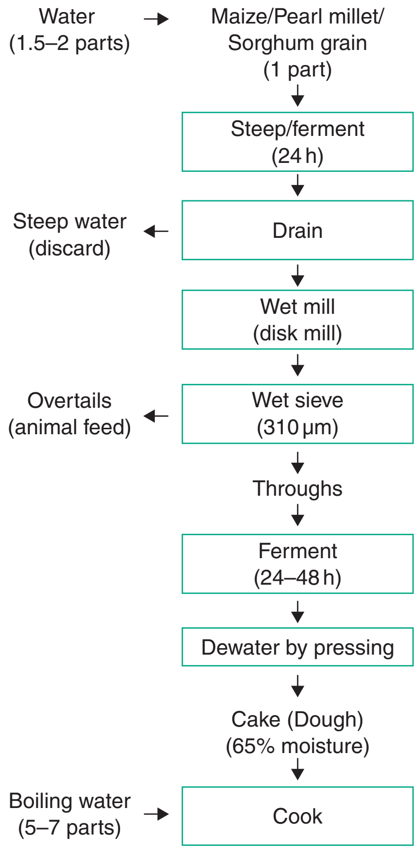

Figure 7 Traditional process for producing ogi.

between 5% and 8% or higher, depending on the desired consistency. It is a staple food in Nigeria, eaten as breakfast porridge or as a food for infants and the infirm. It is served hot, often accompanied by bean cake.

The traditional production process starts with steeping the grain (a first fermentation), wet milling, and sieving to remove coarse material (Figure 7). The throughs are then fermented by a spontaneous fermentation. The precise microorganisms responsible are not known. However, *Lactobacillus*, *Enterobacter*, and *Leuconostoc* species have been found to be present in sorghum ogi fermentations, with the latter being replaced by *Corynebacterium* species later in the fermentation. The final pH should be pH 4.1–4.5. Traditionally, ogi slurry is pressed into a dough (known as a cake), which is sold commercially by street vendors. To prepare ogi, the dough is made into a smooth slurry with cold water and added slowly to boiling water and cooked for ~2 min. It may be sweetened if so desired.

Since the dough has a shelf life of only two days, research had been conducted by the Nigerian Federal Institute of Industrial Research to produce shelf-stable products. A long-life powder has been produced by spray drying. However, this product still requires to be cooked. An "instant" powder produced by roller drying has been developed. As it is precooked, it only requires the addition of hot water to prepare the ogi. A further development is a more nutritious composite instant ogi powder incorporating full-fat soya flour. This nearly doubles the protein content, increasing the percentage contribution to the recommended dietary allowance (RDA) of an infant from 25% to 48%. Additionally, the ogi biological value, protein efficiency ratio (PER), and digestibility are dramatically improved. Soy-ogi has become a popular product, sold in supermarkets.

Beverages

"Mageu," also commonly known as "amahewu" or "magou," is a southern African maize-based fermented beverage or gruel (Figure 8). It is produced in the home and in institutions such as hospitals and mine hostels. It is also produced on a large industrial scale in South Africa and Botswana. Industrially produced mageu has a solids content of ~8% with an energy content of 1595 kJ l^{-1} and a pH of ~3.5. Mageu is regarded as a nutritious, energy food, ideal for those doing hard manual work.

The traditional method of making mageu simply involves preparing a maize meal porridge of 8–10% solids, allowing it to cool to room temperature and then adding a small quantity of wheat flour. The porridge will then undergo a lactic acid fermentation. The wheat flour acts both as a starter and as a source of enzymes, in particular β-amylase which produces a small amount of maltose which is utilized in the fermentation.

A typical modern industrial process is shown in Figure 9. The major improvements from the traditional process are the introduction of thermophilic LAB cultures which only produce lactic acid and extension of the shelf life of the product by pasteurization and/or chemical preservation. It has been stated that the LAB is *L. delbrueckii*, although there is a strong indication that the cultures are mixed and also contain *Thermobacterium* as they are very heat- and acid-tolerant. The industrial product also differs from the traditional mageu in that it is often artificially flavored with flavors such as banana, cream, pineapple, and guava (Figure 8).

Another development in mageu manufacture is using pregelatinized maize meal. The use of this so-called powder mageu is ideal for institutional feeding as it obviates the need for porridge cooking equipment. The pregelatinized maize meal is normally produced by "dry-cooking," either high-temperature, short-time extrusion, or gun puffing.

Figure 8 Commercial mageu with maize meal, the raw material, in the background.

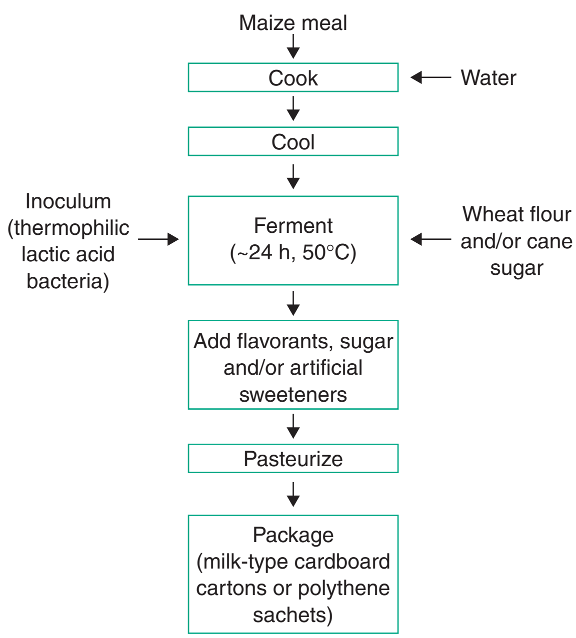

Figure 9 Industrial process for making mageu.

Potential for Development

Traditional LAFCFANAB seem to be at crossroads. Although remaining very popular as home or small-scale commercially produced products, industrialization has been limited. Further, there are some indications that with rising incomes and changing lifestyles, people in developing countries turn away from traditional fermented foods. For example, in South Africa over a period of 5 years from 1996 to 2001, industrial mageu production fell from 109 million liters (Ml) to only 76 Ml. Some scientists view this trend with great concern. It has been stated that if consumers in developing countries abandon traditional fermented foods for "smart" products popularized in Europe and America, such as cola, it could have a significant negative impact on their daily nutrition.

Perhaps this is overstating the case, but LAFCFANAB do have some unique functional and nutritional properties that food scientists should exploit through the development of innovative products, which satisfy the needs of today's consumers in both the less-developed and more-developed world. For example, injera seems ripe for development into a commercial product as it is a leavened bread produced from non-gluten containing cereals such as sorghum. Thus, injera could be very suitable for countries in the semi-arid tropics where wheat cannot be produced economically and it could be attractive to people who are allergic or intolerant to wheat products. Additionally, injera could make a great fast-food as it can be used as a "wrap" for meat or vegetable fillings.

A nutritional aspect of fermented cereal foods that is already being exploited in Europe is as Functional Foods, foods that have a health-promoting properties over and above their basic nutrient content. In Finland, a range of oat-based, yogurt-like products called oat Vellie is being produced (Figure 10). Three aspects of oat Vellie are novel. First, it is entirely cereal and thus is an ideal alternative to yogurt for people who are allergic or intolerant to dairy products. Second, it is rich in oat fiber which has a cholesterol-lowering property, and third, in addition to LAB, it

Figure 10 Oat Vellie. (Reproduced with kind permission of Bioferme oy.)

contains the probiotic bacterium *Bifidobacterium lactis*. Many benefits have been claimed for *Bifidobacteria*, but perhaps the most important, especially for the "at risk" in developing counties, is that they are protective against gastrointestinal infections.

FOOD SAFETY THROUGH THE PRODUCTION CHAIN

R Rooney, World Health Organization, Geneva, Switzerland
P G Wall, Food Safety Authority of Ireland, Dublin, Republic of Ireland
C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

Contaminated food is one of the most widespread public-health problems of the contemporary world and it causes considerable morbidity and mortality. Globally, millions of people are affected by foodborne disease. Food poisoning can be very serious in vulnerable groups such as the elderly, infants, young children, pregnant women, and immuno-compromised individuals. The proportion of vulnerable groups such as the elderly and immuno-compromised is increasing in industrialized countries.

Looking at food consumption broadly, recent high-profile food-safety emergencies and scares have shaken consumer confidence in the production of food, focusing attention on the way food is produced, processed, and marketed. These incidents have included an epidemic of bovine spongiform encephalitis (BSE) in cattle, possible links between BSE and

Table 1 Risks to food safety throughout the grain production and processing chain, and possibilities for risk minimization

Stage of grain production	*Possible risks*	*Risk-minimization strategy*
Breeding	Plant and grain diseases may leave residual contaminants	Select genotypes that are resistant or tolerant to diseases
Breeding	Antinutritional compounds may be present in mature grains	Select for genotypes that do not contain significant amounts of antinutritional components
Pure-seed production	Toxic seeds may be contaminants in harvested grain	Eliminate contaminating seeds from seed for sowing
On-farm production	Toxic seeds may be contaminants in harvested grain	Appropriate preparation of ground before sowing
On-farm production	Agricultural chemicals may remain in harvested grain	Minimize use of chemicals, especially those that persist to the mature grain
Harvesting	Spoilage organisms affecting mature grain at harvest	Harvest grain when dry, before there is opportunity for molds, etc., to attack
Grain receival	Contaminated grain is combined with sound grain	Test grain at delivery for defects and contaminants; eliminate contaminated grain from grades for human consumption
Storage	Pesticide residues may remain in grain above minimum levels	Avoid methods of grain protection involving persistent residues
Transport	Grain may be contaminated by materials in transport containers	Ensure cleanliness and sealing of transport containers
Milling	Microorganisms and filth as contaminants	Remove dust, very small grains and nongrain material before milling
Processing	Contaminants become incorporated into food products; inappropriate additives may be used as processing aids	Use best-practice procedures to ensure absence of contaminants; minimize the levels of food additives
Marketing	Consumers may be uncertain about additives and possible contaminants	Use labeling to provide assurance about maximum levels of relevant contaminants and additives

variant Creutzfeldt-Jakob disease (CJD) in humans, and the discovery of dioxin-contaminated animal feed entering the food chain. New food-borne pathogens such as *Escherichia coli* O157:H7, *Cyclospora cayentanensis*, and *Listeria monocytogenes* have also emerged. Infection with *E. coli* O157:H7 can be fatal in young children, the elderly, and the immuno-compromised, and since the 1990s, serious outbreaks have occurred in the USA, Scotland, and Japan. *L. monocytogenes* can result in meningoencephalitis and/or septicemia in newborns and adults and abortion in pregnant women. Parasites such as *C. cayentanensis* and *Cryptosporidium parvuum* have emerged as a serious health threat for immuno-compromised individuals, particularly AIDS patients.

Most of these highly publicized cases are not related directly to the grains industry, but there is significant potential for food safety risks to arise at any of the various stages of grain production and processing (Table 1 and Figure 1). In addition to risks of biological origin, chemicals in foods have also caused concern, including herbicides and grain protectants, with the possibilities of residues remaining in grain-based foods. Specific chemicals are also added to grain-based foods during processing in the form of improvers, nutrients added as part of food fortification, flavorings, colors, and various other food additives. Well "downstream" of grain production, grain-based foods come into close interaction with the full range of foods, opening up the complete range of risks relevant to the food industry in general. For example, traditional grain-based foods like bread and pastry become subject to all the risks associated with meat products when they are consumed as ham sandwiches and meat pies.

Food safety is a sensitive political and economic issue as well as an important public-health issue. Many consumers and consumer lobby groups continue to express concerns about the long-term impact of chemical and biological contaminants in food, in addition to potential chronic and acute effects on vulnerable groups. This article describes food-safety issues relating to the grains industry, as well as expanding its scope to include the wider issues in the food-processing industry. Integral to these considerations are the biological, chemical, and physical hazards in food, and possible control and prevention strategies for industry.

Food-Safety Hazards in Grain Production and Processing

Most food-safety hazards arise from contaminating agents. The term "contaminant" covers harmful substances or microorganisms that are not

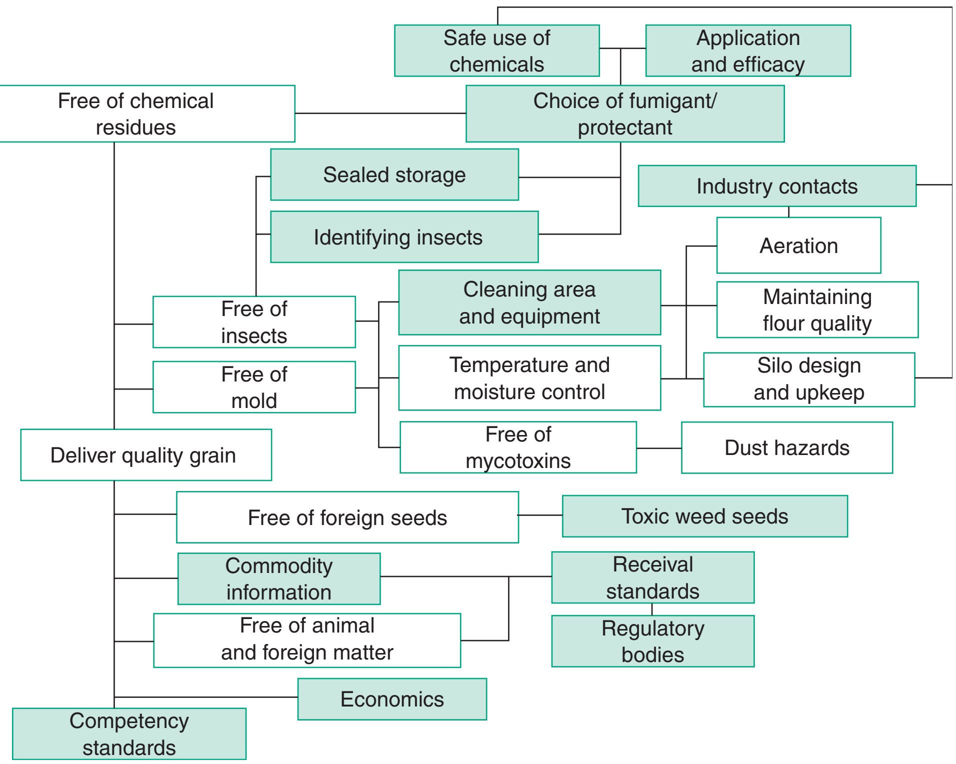

Figure 1 A summary diagram coordinating the many aspects of food safety and quality control required in the grain-production industry. (Reproduced with permission from the Value-Added Wheat CRC, Sydney, Australia.)

intentionally added to food. Contaminants may enter the food accidentally during growth, cultivation, transport, or preparation. They may accumulate in food during storage, form in the food through the interaction of chemical components, or may be concentrated from the natural components of the food. Several risks associated specifically with the grains industries are listed in Table 1, together with strategies for limiting these hazards. Figure 1 summarizes the many aspects of food safety and quality control that must be coordinated in grain production. Most of the risks can be summarized under three headings, namely, those due to contaminants of biological, chemical, and physical nature.

Biological Hazards

Broadly in food safety, there is a wide range of biological agents of concern to public health. These include pathogenic strains of bacteria, viruses, helminthes, protozoa, and algae, and certain toxic products they may produce. In the case of grain-based foods, most of these are likely to be introduced via the nongrain components of the food. In such cases, food-borne infections are caused when microorganisms are ingested. Microorganisms may be introduced directly from infected raw materials, from workers, from other foods, or from the environment during the preparation or processing of food. Poisonous substances may also be produced by the growth of bacteria and molds in food. Table 2 lists pathogenic organisms of public-health importance, which may be transmitted through contaminated food.

An obvious source of toxicity for harvested grains is contamination with weed seeds that are either toxic or at least unpleasant due to their contribution of taint. Furthermore, seeds with a dark seedcoat are likely to cause dark specks in the flour. Table 1 indicates this risk, plus the likely remedies of ensuring that seed for sowing is free of contaminating weed seeds and that the ground where the seed is to be sown must be correctly prepared to avoid the risk of these weed seeds germinating and growing together with the crop seeds.

Further biological hazards of grains arise due to defects that occur during growth. For example, for wheat and barley, these include infections such as ball smut (also bunt or stinking smut), caused by *Tilletia caries* or *T. foetida*, which replace the endosperm of the grain by black spores with an unpleasant odor.

A classical disease of cereals, especially rye, is caused by ergot (*Claviceps purpurea*) infecting the flowers of the cereal grain, producing an ergot body in place of the grain. These ergot bodies are recognizable in grain samples as black bodies (sclerotia) larger

Table 2 Examples of major biological hazards in foods

Bacteria (spore-forming)	Viruses
Clostridium botulinum	Hepatitis A and E
C. perfringens	Norwalk virus group
Bacillus cereus	Rotavirus
Bacteria (nonspore-forming)	Protozoa and parasites
Brucella abortis	*Cryptosporidium parvum*
B. suis	*Diphyllabothrium*
Campylobacter spp.	*Entamoeba histolytica*
Pathogenic *Escherichia coli* (*E. coli* O157:H7, EHEC, EIEC, ETEC, EPEC)	*Giardia lamblia*
	Ascaris lumbricoides
	Taenia solium
Listeria monocytogenes	*T. saginata*
Salmonella spp. (*S. typhimurium, S. enteritidis*)	*Trichinella spiralis*
Shigella (S. dysenteriae)	
Staphylococcus aureus	
Streptococcus pyogenes	
Vibrio cholera	
V. parahaemolyticus	
V. vulnificus	
Yersinia enterocolytica

and longer than the normal grain length, but they break up easily, and of course, they disappear during milling. Ergot may also be present in grain consignments due to the infection of contaminating grains, especially ryegrass. Ergot is a source of toxic alkaloids (Table 3), so there are strict limits on the maximum levels permissible in grains for human or animal consumption.

A range of microorganisms may risk the food safety of grains as early as at harvest time. Microbiological contamination is not uncommon in harvested grain; contaminants may include a wide range of species, including *Bacillus* species, coliforms, molds, and yeasts. These organisms cannot readily be removed from the grain at harvest, so they may continue through milling and processing. Nevertheless, the levels of microbiological contamination are generally low for dry sound grains of cereals, for example.

On the other hand, grain that is harvested very moist, e.g., over 17% moisture, may suffer from the very serious condition of the production of mycotoxins, produced by fungi of the genera *Aspergillus*, *Fusarium*, and *Penicillium*. The specific mycotoxins produced by these fungi are listed in Table 3. Mycotoxins are active at very low concentrations, even at a few ppb. They are not always produced in moldy grain, but the risk is obviously best avoided by keeping grain dry and free from molds. Immuno-assay kits are now available for the determination of various mycotoxins in "field" situations within minutes, providing the opportunity of checking for this risk "on-the-spot," in contrast to the need some years ago of reliance on laboratory-based analysis taking some days for results.

Excessive grain moisture is likely to cause deterioration on storage and during transport, due to increased risk of attack by insects and molds. For this reason, there are critical limits for the maximum moisture for grain that may be received at the grain elevator or mill. This maximum varies between grain-growing regions and between grain species, but it is generally in the range 12–14.5%. Artificial drying is thus a requirement in many grain-growing regions.

At the stage of flour milling, there is the possibility of reducing the bacterial count for wheat. This is because the highest levels of contamination by microorganisms are found in the light (low-density) fraction of raw wheat and in the grain dust. Therefore, special attention must be paid to the removal of this material prior to milling. For infected grain, it has proved possible to reduce the bacterial count greatly by applying the various cleaning methods in a selective manner (removal of impurities, aspiration, classification, and scouring).

Genetically modified (GM) grains are considered as a "hazard" by some consumers. As a result of the controversy about the new genetics, there has been the need to identify GM varieties of some grain species, especially maize and canola, so that these are kept

separate throughout grain receival, storage, transport, and processing, so that the food products can be labeled appropriately (Table 1).

Chemical Hazards

Food-borne toxicants can be categorized according to their chemical nature. Some food-borne toxicants are inorganic, e.g., lead and arsenic, whereas others are organic, e.g., polychlorinated biphenols (PCBs). Major categories of man-made chemicals that occur in foods are shown in Table 4. Chemical hazards may result from pollution arising from industrial and other human activities (e.g., lead, mercury, cadmium, and PCBs), from agricultural practice (e.g., pesticides, fertilizers) or from food processing and packaging (e.g., nitrosamines and certain polycyclic aromatic hydrocarbons). These contaminants may present a potential hazard for human health if exposure exceeds tolerable levels.

Most obviously for the grain industry, there is the risk of residues from agricultural chemicals occurring at levels above the specified minimal residue limits. These grain protectants are used justifiably to avoid another hazard, namely, insect infestation. The value of chemicals for this purpose is the residual protection of grain during extended storage and transport. However, there are alternatives, including fumigation with compounds that leave virtually no residue, or storage in an enriched atmosphere of carbon dioxide.

Some grains contain natural chemical hazards, such as a variety of antinutritional components. Some of these are naturally occurring inhibitors of digestive enzymes. In such cases, there may be the need for various pretreatments to overcome the antinutritional effects of such compounds. There is the added possibility that suitable application of plant-breeding methods may be able to select for genotypes that lack the potentially toxic components (Table 1). Celiac disease is a specific case of a naturally occurring "toxin" that affects certain people; in this case, the problem compound is the gluten–protein complex. These gluten-like proteins are present in wheat, rye, triticale, barley, and possibly oats.

Table 4 Examples of chemical hazard in foods

Industrial/environmental pollution	Food additives
Polychlorinated biphenyls (PCBs)	Vitamins and minerals
Agricultural chemicals	Contaminants
Pesticides	Lubricants
Fertilizers	Cleaners
Antibiotics	Pest-control chemicals
Growth hormones	Coatings
	Paints
Inorganic chemicals	
Lead	*Chemicals migrating from packaging*
Tin	
Mercury	Plasticizers
Zinc	Vinyl chloride
Cadmium	Printing/coding inks
Arsenic	Adhesives
Cyanide	Lead
Additives	Tin
Feed additives	
Veterinary drugs

Physical Hazards

Examples of physical hazards are foreign matter, including dirt and glass that accidentally get into food. They can be the result of environmental contamination during production, processing, storage, packaging, and transport, or from fraudulent practices. Further examples that are specifically relevant to grains include materials of biological origin, such as rodent hairs and insect pieces. The identification of these fragments may involve microscopical examination, plus reference to catalogues of commonly found contaminating materials. Simple tests are available as backup for cases of identification, such as the use of ultraviolet examination for the presence of rodent urine.

The potential for ionizing radiation to have long-term health effects, not only on the people living nearby but also the health of the ecosystem, is considerable. Following the nuclear reactor failure at Chernobyl (Ukraine) in 1986, food contaminated with radionucleides with long half-lives, such as cesium 137, is the major source of exposure for people living in this area. Table 5 lists examples of physical hazards in food.

Table 5 Examples of physical hazards

Material	*Sources*
Glass	Bottles, jars, light fixtures, utensils, gauge covers, etc.
Wood	Field sources, pallets, boxes, building materials
Stones	Fields, buildings
Metal	Machinery, wire
Insulation	Building materials
Bone	Improper processing
Plastic	Packaging, pallets, equipment
Personal effects	Employees

Ensuring Food Safety

The ultimate objective of the food industry and government regulators is to insure that food reaching the consumer is safe and wholesome. Feed manufacturers, farmers, and food operators have the primary responsibility for food safety. Government regulators and consumer associations also have a role to play. However, food-safety emergencies over the last 2 decades have exposed weaknesses in the food industry from farm to fork. They have shown that considerable progress is needed to come to grips with the preventive aspects of food-borne disease.

World Trade and International Standards

The Food and Agriculture Organization (FAO) and the World Health Organization (WHO) have complementary food-safety mandates to protect the health of consumers, to prevent the spread of disease and to ensure that the procedures followed in food trade are fair. The Codex Alimentarius Commission (CAC), which manages the joint FAO/WHO food-standards program, sets international standards for food. It was established in 1961–62 by the FAO and WHO, and it aims to protect the health of consumers and ensure fair practices in food trade.

The World Trade Organization (WTO) rules provide a framework for the application of food-safety measures in international trade. The standards and guidelines of the CAC are recognized by the WTO as the international benchmark standards, guidelines, and recommendations to be used as the basis of harmonizing food safety measures affecting human health and world food trade.

International standards influence trade as well as food safety, and national governments are under pressure to ensure that their regulatory programs are comprehensive and conform to these global standards. Owing to the complexity of the food-production chain, the traditional role of government as the food-safety inspector has changed, with the food industry taking more responsibility for the implementation of quality-assurance programs throughout food production, distribution, and retail. However, a strong national food-control agency is required to bring about cooperation between government departments and industry, and to set standards and targets for health protection.

Risk Analysis and Food Safety

The concept of risk analysis is gaining acceptance internationally as a very important component of national food-control programs, and its principles are being integrated more fully into the work of food safety regulators and policy-makers. This principle consists of three components: risk assessment, risk management, and risk communication.

Risk Assessment

Risk assessment is a science-based investigation that can provide an estimate of the probability and impact of adverse health effects attributable to potentially contaminated foods. The aim is to identify, in some quantitative or comparable way, the relationship between hazards and actual exposure to harm. The detail and complexity of a given risk assessment will vary, depending on the availability of time, resources, and scientific information. A full risk assessment may not always be carried out, because data may be incomplete, and resources may be inadequate. However, decisions that are made by well-focused assessments, using whatever data are available, will usually be more reliable and transparent than subjective judgment. Risk assessment links into the other two components of risk analysis, the others being risk management and risk communication. The stages of the risk-analysis process are closely linked and cannot be separated easily. Consideration of the ways in which a risk might be managed is necessarily part of the assessment and communication.

Risk assessment consists of four steps: hazard identification, hazard characterization, exposure assessment, and risk characterization (Figure 2). In hazard identification, the association between disease and the presence of a pathogen or contaminant in food is documented. Hazard characterization involves obtaining quantitative information about the hazard, including, where possible, information on dose–response relationships. Exposure assessment estimates the intake or exposure to a chemical or pathogen, in terms of its magnitude, duration, and frequency, for the general population, for subgroups or for individuals. Risk characterization is the integration of hazard identification, hazard characterization, and human intake/exposure assessment. It assesses the likelihood of a particular event. This is the framework adopted by the CAC, the international standard setting body for foods in international trade.

Risk assessment is already fairly well developed for chemical hazards. The estimation of chemical health risks often relies on data obtained in the customary rodent-feeding assays using standardized safety margins. Such assessments call for an extrapolation of response data derived from animal studies to humans. The setting of advisory standards, such as acceptable daily intakes (ADIs) for food additives, pesticides, and veterinary residues in food, is a key component in the overall risk assessment of many chemicals subject to

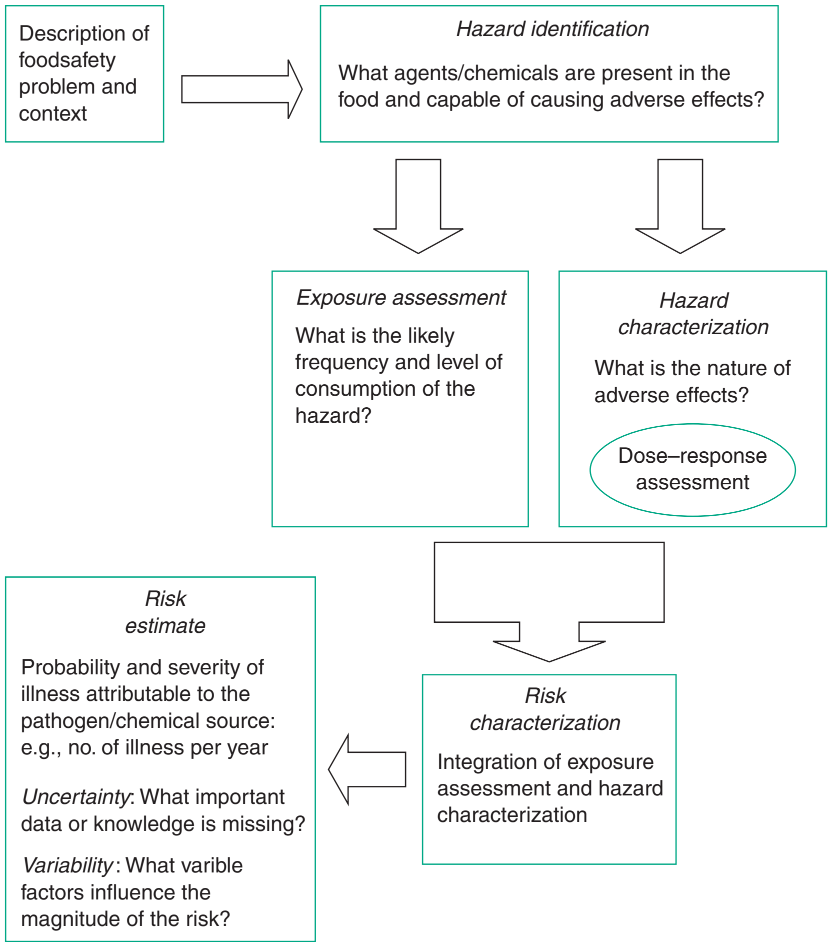

Figure 2 Steps of food-safety risk assessment. (Adapted from Lammerding AM and Fazil A (2000) Hazard identification and exposure assessment for microbial food safety risk assessment. *International Journal of Food Microbiology* 58: 147–157.)

regulatory control. Quantitative risk assessment is an emerging tool in the field of microbial food safety. Estimation of microbiological hazards presented by foods is more complex, because of biological diversity and variability. However, such estimations are usually more accurate than estimates on adverse effects from chemicals in foods. This is because incidents are frequent, in sharp contrast to those resulting from exposure to chemicals. This allows for a better risk assessment.

Risk Management and Risk Communication

Food scares such as salmonellae in eggs, *E. coli* O157 in beef and BSE have all damaged consumer confidence in regulatory agencies. Such problems were compounded when government departments had the dual role of promoting farming and the food industry as well as protecting the consumer. Such roles resulted in a conflict of interest. A regulatory agency should ideally be independent of trade and economic interests and have consumer interests as its primary function. Although it is the primary responsibility of the food industry to comply with the laws and regulations, the regulatory agency should provide an integrated inspection system from farm to fork. This may best be achieved by establishing a national food standards agency that has responsibility for all sectors of the food chain. Many countries have established such agencies and coordinate the work of all government departments involved in food safety. Such coordination overcomes the problems of duplication of work and conflicts of interest.

A food-borne disease surveillance program is also an essential part of a food-control program. Surveillance is necessary to identify food-borne contaminants, their sources, and their modes of transmission in order to determine the best short- and long-term control measures. Interpretation of trends and investigation of outbreaks can help identify the mechanisms by which contamination and disease transmission occurred. When an outbreak occurs or a chemical

Table 6 Seven principles of the hazard analysis and critical control point (HACCP) system

Principle 1 **Conduct a hazard analysis** Prepare a list of steps in the process where significant hazards occur and describe the preventive measures. Assess the likelihood of occurrence of the hazard(s) and identify the measures for their control.
Principle 2 **Identify the Critical Control Points (CCPs) in the process** Determine the points, procedures, or operational steps that can be controlled to eliminate the hazard(s) or minimize its (their) likelihood of occurrence.
Principle 3 **Establish critical limits for preventative measures associated with each identified CCP**
Principle 4 **Establish CCP monitoring requirements** Establish procedures from the results of monitoring to adjust the process and maintain control.
Principle 5 **Establish corrective actions to be taken when monitoring indicates a deviation from an established critical limit**
Principle 6 **Establish effective record-keeping procedures that document the HACCP system**
Principle 7 **Establish procedures for verification that the HACCP system is working correctly**

contamination incident is identified, it is vital to learn from the investigation what went wrong in order to devise strategies to prevent similar events in the future.

Quality Assurance via HACCP Principles

Food quality and safety can only be insured through the application of quality-control systems throughout the entire food chain. They should be implemented at farm level with the application of good agricultural practices, good manufacturing practice at processing, and good hygiene practices at retail and catering levels. One of the most effective ways for the food sector to protect public health is to base their food-management programs on hazard analysis critical control point (HACCP).

HACCP consists of seven principles that outline how to establish, implement, and maintain a quality-assurance plan for a food establishment. It is a systematic approach to the control of potential hazards in a food operation and aims to identify problems before they occur. Control is proactive, since remedial action can be taken. The HACCP principles have international recognition, and the seven principles are listed in Table 6.

HACCP plan adoption has greatly improved the food industry's ability to design programs to insure the safety of food. It was introduced in the early 1970s and has become the premier system for preventing food-borne hazards, particularly those of microbiological origin. The basic process in creating HACCP plans is that the main hazards associated with a food product are determined, and key steps in the production, processing, distribution, marketing, and preparation of food are controlled within pre-established limits to insure the safety of food. A program of monitoring, verification, and record-keeping is then implemented to insure that the system functions correctly.

The Codex General Principles of Food Hygiene recommend a HACCP-based approach to enhance food safety. This management tool is internationally recognized as essential to ensure food safety and is recommended by governments, industry, and consumers.

Conclusion

Food safety in the early twenty-first century is an international challenge requiring close cooperation between countries in agreeing standards and in setting up transnational surveillance systems. The lessons of recent decades are plain to those engaged in the food industry. No longer can farmers grow just what they want or use technical aids to farming without taking into account the effect on the quality of the food produced. Food will always present some risk, and it is the task of the food industry to keep the level of risk to the minimum, which is practicable and technologically feasible. It should be the role of official bodies and the food industry to use risk analysis to determine realistic and achievable risk levels for food-borne hazards and to base food-safety practices on the practical application of the results of these analyses, thus continuously improving the safety of food and thereby lowering the disease risk. By providing effective

food-control, countries not only provide public-health benefits, but also enable themselves to participate in international food trade with greater confidence.

The lasting solution to the problems, which have shaken the food industry in recent years, can only be overcome if all those involved – farmers, food processors, wholesalers, transporters, retailers, caterers, scientists, regulators, and government – work together towards common goals.

FORTIFICATION OF GRAIN-BASED FOODS

C M Rosell, Instituto de Agroquímica y Tecnologia de Alimentos (IATA-CSIC), Burjasot, Valencia, Spain

Introduction

Fortification is a way of providing different nutrients using staple foods as agents, with the aim of supplementing the diet through the intake of these nutrients. Such supplements could be an important tool in combating nutrient deficiencies. In this article, the following aspects concerning fortification will be considered:

- criteria for fortification;
- cereals as vehicles for food fortification;
- processes for cereal fortification;
- additives used as a nutrient source; and
- legislation concerning cereal fortification.

Definition

Fortification can be defined as the addition of one or more vitamins and/or minerals to a food, regardless of its usual content in the food. Additions are carried out based on generally accepted scientific knowledge of the role of vitamins and minerals in attaining good health. Foods are fortified for the following reasons:

- to prevent or correct a demonstrated deficiency of one or more vitamins and/or minerals in the population or specific population groups; and
- to improve the nutritional status of the population and dietary intakes of vitamins or minerals due to changes in dietary habits.

Enrichment is a term usually interchanged with fortification. The term "enriched flour" was coined during the Second World War when the American government decided to improve the soldiers' diet by including different nutrients in bread. Initially, the enrichment consisted of the addition of the three major B-vitamins (thiamine, riboflavin, and niacin) and iron, despite the scarce scientific information concerning the real nutritional improvement obtained with that proposal. Later, numerous scientific studies have been conducted for verifying the utility of those measures.

Ideally, enrichment should be equivalent to restoration. This means that the addition of vitamins and minerals, present in the edible portions of the food, will restore the levels lost during manufacturing, storage, and handling.

The other relevant term in this subject is "nutritional equivalence," which means "being of similar nutritive value in terms of quantity and bioavailability of vitamins and minerals." Since fortification is a broader term, it will be used here while referring to the addition of nutrients.

Criteria for Food Fortification

Minerals and vitamins may be added to foods only for the purpose of (1) restoration of nutrients lost during processing; (2) nutritional equivalence of substitute foods; (3) fortification; and (4) ensuring the appropriate nutrient composition for a special purpose food.

Some considerations should be taken into account, prior to addition of any nutrient to foods:

- The nutrient added should be present at a level that will not result in either an excessive or an insignificant intake, considering the amount provided from other dietary sources. The maximum safe amount to be added should be set considering the levels established by generally accepted scientific data and bearing in mind the diverse degree of sensitivity shown by different consumer groups.
- Nutrients should not be added to fresh products including meat, fish, fruits, and vegetables, neither to beverages containing more than 1.2% by volume of alcohol.
- The nutrient added should be biologically available from the food and should not interfere in the metabolism of any other nutrient.
- The nutrient added should be sufficiently stable during packaging, storage, distribution, and end use, and should not affect both the sensory characteristics and the shelf life of the food.
- Technology and processing facilities should be available to permit the addition of the nutrient and also methods of measuring and controlling the levels of nutrient added.
- Fortification should not be used as a tool for providing nutrients in substitution of the natural nutrient sources, as this would lead to a change in the dietary patterns and thus jeopardize good dietary practices.

It is clear that the policy for food fortification has a completely different objective when considering

developed and developing countries. In developed countries, the social changes (industrialization, high per capita income, consumption of fast food outside the home) over the years have led to increasing consumption of more highly processed foods. This has been used to justify the necessity of food fortification for ensuring the adequate intake of nutrients, mainly vitamins and minerals. However, there is no general consensus about the extent to which food fortification should be allowed. There are differing opinions that manufacturers could use fortification as a promotional tool resulting in an excessive intake of certain nutrients that would represent a risk for consumer health.

There are different considerations involved in the establishment of food fortification programs in developing countries compared to those in the developed ones. Food fortification is one approach towards solving nutrient deficiencies in developing countries, and so far the implementation of these programs has been very successful in correcting nutritional deficiencies within a very short period. In the developing countries, care should be taken that the food selected as a medium for the nutrient addition is stable and consumed by the population at risk, and that the amount of nutrient added is sufficient to correct the possible deficiency.

Cereal-Based Products as Vehicles of Minerals and Vitamins

One of the most critical decisions concerning food fortification is the selection of the appropriate food to act as a carrier of the nutrient. The basic criteria for identifying the food products for fortification include selecting a food that is commonly eaten by the target population group, affordability, and availability all through the year.

Cereals and cereal-based products constitute a major component of diet around the world. Cereals have been used as a basis of human diet from the ancient times. Nowadays, cereal production is estimated to be 1862 million tons (Mt), out of which ~950 Mt is consumed by people. In fact, cereal consumption is ~150 kg per capita per year (Figure 1), with the highest consumption in Asia, in contrast to Oceania, where that value drops to 85 kg per capita per year. These values reflect the significance of cereals to the human diet.

Globally, cereals account for 48% of total energy intake. When the contribution of the cereals to the daily energy intake is analyzed continent-wise (Figure 2), it is evident that cereals provide the maximum percentage of calories in Asia and Africa, and that their contribution decreases to 32% in Europe and America. Slight changes to that trend are observed when analyzing the contribution of cereals to the percentage of protein intake. Cereals are a cheap source of proteins compared to animal proteins. In Africa, cereals supply up to 33 g of proteins per person daily; that means 54% of the daily protein intake. Similar values are found in Asia, where cereals provide 51% of the daily protein intake, while that value drops to 20% in the developed countries.

When the cereal contribution is analyzed (Figure 3), it can be observed that rice accounts for 26% of the total energy intake in the developing countries, and for only 4% of the total energy intake in the developed countries. Wheat provides 23% of the total energy intake in developing countries, while that value decreases to 18% in the developed countries. The other cereals have a minor contribution to the energy and protein intake; only maize is an important supplier of energy in the developing countries.

These data illustrate the popularity of cereals in the diet worldwide, and therefore the importance of cereals, mainly rice and wheat, as a staple medium for fortification in both developed and developing countries.

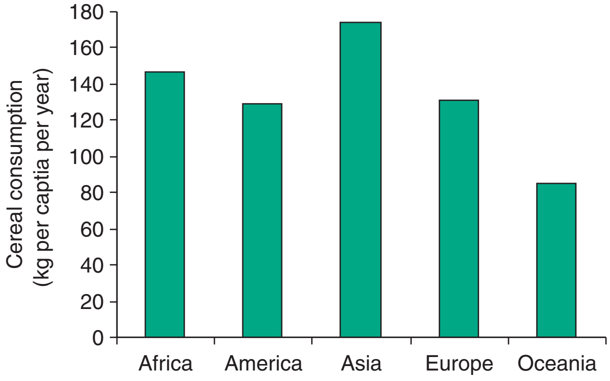

Figure 1 Cereal consumption (kg per capita per year) in different continents. (Data from FAOSTAT (2003).)

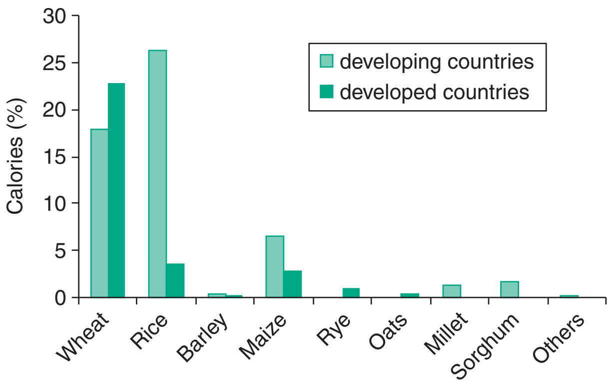

Figure 3 Percentage of calories provided by different cereals to the diet. (Data from FAOSTAT (2003).)

Table 1 Vitamins and minerals that may be added to foods

Vitamins	*Minerals*
Vitamin A	Calcium
Vitamin D	Magnesium
Vitamin E	Iron
Vitamin K	Copper
Vitamin B_1	Iodine
Vitamin B_2	Zinc
Niacin	Manganese
Pantothenic acid	Sodium
Vitamin B_6	Potassium
Folic acid	Selenium
Vitamin B_{12}	Chromium
Biotin	Molybdenum
Vitamin C	Fluoride
	Chloride
	Phosphorus

Vitamins and Minerals Added in Cereal Fortification

Once the food to be fortified is selected, the nutrient deficiencies affecting the population must be determined. Nutrient deficiencies are different in the developing and developed countries. While vitamin A, iodine, and iron are found to be deficient in the former, in the developed countries B-vitamins, iron, calcium, and folic acid are currently added to wheat flour to counter deficiency. There are only certain vitamins and minerals that may be added to foods (Table 1).

In general, all the rice-consuming countries have a vitamin A deficiency, which is associated with corneal lesions that can lead to partial or total blindness, and with reduced resistance to infectious diseases. This would, in consequence, lead to an increase in morbidity and mortality. Another deficiency associated with rice-consuming countries is anemia due to iron deficiencies. This has been linked to reduced resistance to infection and also affects the cognitive development and physiological functions in children and, in severe cases, causes maternal deaths. Iodine constitutes the third major deficiency in rice-consuming countries. This mineral is necessary for proper fetal development and also for normal physical and mental activities in adults.

In the developed countries, iron supplementation has been a measure adopted in some countries to reduce the prevalence of iron-deficiency anemia. B-vitamins (thiamine, riboflavin, and niacin) and calcium are also supplemented in developed countries to ensure the adequate intake of those nutrients. Recently, some studies, confirming the role of folates in congenital malformations (neuronal tube defect) and the development of chronic diseases in elderly people like Alzheimer's, have recommended the supplementation of folic acid in cereal-based foods. However, the effectiveness of this fortification program in the decrease of homocysteine concentration and its relationship with a reduction in the incidence of cardiovascular disease will not be available for several years.

Methods for Cereal Fortification

Cereals are not directly consumed as grains; processing is generally required to transform the grain prior to its consumption. That process results in a substantial reduction of different nutrients, as B-vitamins and iron, mainly concentrated in the outer layers and germ. Cereal-fortification methods have been developed to restore the nutrients that have been removed during milling and to improve the nutrient intake level of specific population.

Rice Fortification

Although rice and wheat are the most appropriate cereals for food fortification, rice requires special methods for fortification as it is commonly consumed as a whole grain and is extensively washed prior to cooking or strained after cooking.

There are different methods for rice fortification; the earliest one was the production of parboiled rice. In the parboiling process, rice is steamed under pressure to gelatinize the starch within the kernel; this process allows the transference of nutrients from the bran layer to the starchy endosperm.

Other methods currently used are the powder and grain enrichment methods. In the powder enrichment method, a powder preblended with mixtures of vitamins and minerals is added to the rice. For white parboiled rice, the blend is added immediately after milling because the heat and moisture content of the grain surface at that moment facilitates the

adherence of the powder mixture. However, the nutrient supplementation in this method can be washed off if the grains are rinsed before cooking.

The grain enrichment method involves the addition of a powdered mixture of vitamins and minerals and a subsequent coating of the grain with a water-insoluble substance. Usually grains enriched by this method contain a high-nutrient concentration and they are mixed in a proportion of 0.5% with normal milled rice, to finally obtain an enriched product that meets the required standard levels. Different variations of these methods have been developed through the years. For instance, the powdered mixture can be sprayed onto the rice and then fitted by the application of water-insoluble coating like ethanol, isopropanol, palmitic acid, or cellulose derivatives. This method has been successfully used for enriching rice with niacin, thiamin, pyridoxine, vitamin A, vitamin E, folic acid, iron, and zinc by adding alternative layers of nutrients and coatings.

Recently, an alternative method consisting of the development of fortified simulated rice has been recommended. It involves the production of synthetic rice by extrusion of rice flour in the presence of vitamins and minerals to a rice kernel shape. The fortified simulated grains are then mixed with normal milled rice. The disadvantage of this method is that the consistency of the resulting grains after cooking is different from that of the natural product. In addition, the consumer often notices an off-type texture and physically removes those grains before cooking. This is obviated by dyeing them a distinct color, so the consumer clearly knows that it should be present.

Flour and Pasta Fortification

Fortification of flour is usually carried out in mills, where the mixture of the required nutrients is added to the flour. The addition of B-vitamins, iron, and calcium is a common practice in some developed countries. However, the nutrient added must have good stability during storage.

In pasta-consuming countries, pasta and noodles are used for fortification. The production of fortified pasta or noodles requires only the addition of the nutrient at the mixing stage prior to the dough-extrusion process, or instead previously fortified flour can be used for this purpose. Some vitamin losses are produced during the drying process, although the extent of that loss depends on the temperature reached during drying.

Breakfast-Cereal Fortification

The fortification of ready-to-eat breakfast cereals is a well-established practice. In fact, this plays an important role in ensuring the adequate intake of nutrients by the US population.

Vitamins are added to the basic recipe prior to processing when they are heat stable, like niacin and riboflavin, or sprayed onto the processed breakfast cereal in the case of heat-labile vitamins (vitamin A, C, and thiamine), ensuring the uniformity of the coverage. Hydrophobic vitamins, e.g., vitamins A and D, need special consideration as emulsions need to be sprayed on the cereals. In these products, the packaging material is very important, as the moisture content should be below 5% to avoid the texture modification of the product.

Compounds Used as a Source of Vitamins and Minerals

Three different requirements should be considered when selecting the source of nutrients: the chemical compound (1) should be stable during packaging, storage, distribution, and end use, (2) should not modify the sensory characteristics (appearance, texture, taste, and aroma), and (3) should ensure the bioavailability of the nutrient. Different chemical compounds are used as a source of vitamins and minerals depending on their use (Tables 2 and 3).

Table 2 Compounds that may be added to cereals as a source of vitamins

Vitamins	*Chemical compound*
Vitamin A	Retinol
	Retinyl acetate
	Retinyl palmitate
	Beta-carotene
Vitamin B_1	Thiamin hydrochloride
	Thiamin monohydrate
Vitamin B_2	Riboflavin
	Riboflavin 5′ phosphate
Niacin (B_3)	Nicotinic acid
	Nicotinamide
Pantothenic Acid (B_5)	D-pantothenate, calcium
	D-pantothenate, sodium
Vitamin B_6	Pyridoxine hydrochloride
	Pyridoxine 5′ phosphate
	Pyridoxine dipalmitate
Vitamin B_{12}	Cyanocobalamin
	Hydroxocobalamin
Vitamin C	Ascorbic acid
	Sodium ascorbate
	Calcium ascorbate
	Ascorbyl 6-palmitate
Vitamin E	Tocopherol
	Tocopheryl acetate
	Tocopheryl acid succinate
Folic acid	Pteroylmonoglutamic acid

Nutrient stability is very important in the case of vitamin fortification. Vitamins are sensitive to heat, oxidizing and reducing agents, light, and other physical and chemical stress. For instance, vitamins are stable when added to flour but the combination of high humidity and temperature adversely affect the stability of the vitamin A. This vitamin is labile to high temperature, and unstable in the presence of oxygen and light, due to its susceptibility to oxidation. Therefore, when vitamin A is added, a protection provided by packaging materials and appropriate conditions of storage should be used in order to reduce the vitamin loss. Encapsulation of this vitamin in a more hydrophilic coat is a common practice in order to obtain a more water-dispersible product.

The supplementation of B-vitamins to flour is faced with the problem of low stability of these compounds during storage. Hence, higher effectiveness is obtained when B-vitamins are added at the bakery rather than at the mill.

Table 3 Compounds that may be added to cereals as a source of minerals

Minerals	*Chemical compound*
Calcium	Calcium carbonate
	Calcium chloride
	Calcium salts of citric acid
	Calcium gluconate
	Calcium lactate
	Calcium hydroxide
Copper	Cupric carbonate
	Cupric citrate
	Cupric gluconate
	Cupric sulfate
Iodine	Sodium and potassium iodide
	Sodium and potassium iodate
Iron	Ferrous carbonate
	Ferrous citrate
	Ferric ammonium citrate
	Ferrous gluconate
	Ferrous fumarate
	Ferrous lactate
	Ferric diphosphate
	Elemental iron (carbonyl + electrolytic + hydrogen reduced)
	Hydroxocobalamin
Magnesium	Magnesium acetate
	Magnesium carbonate
	Magnesium chloride
	Magnesium salts of citric acid
	Magnesium oxide
	Magnesium sulfate
Manganese	Manganese carbonate
	Manganese sulfate
	Manganese chloride
	Manganese citrate
Phosphorus	Calcium salts of orthophosphoric acid
Zinc	Zinc acetate
	Zinc chloride
	Zinc oxide
	Zinc sulfate
	Zinc carbonate

The bioavailability of added nutrients, particularly iron, varies widely depending on the iron compound used for fortification. The physical and chemical properties of the food to be fortified and the iron form used determine which iron compound would be suitable for the purpose. The selection of the iron form is based on organoleptic considerations, bioavailability, cost, and safety. Iron powders are extensively used in flour fortification, but they are poorly absorbed and their absorption is highly dependent on the meal served (phytates, calcium, and polyphenols decrease the bioavailability of iron). For instance, ferric orthophosphate is often the chosen form for rice fortification due to its light color and water insolubility, but it has a very poor absorption. Ferric pyrophosphate is also used, as it does not affect the appearance, texture, aroma, and flavor of the cooked rice. Ferrous sulfate is also used because of its high bioavailability but it often leads to unpleasant colors and flavors due to reactions with other components of the food matrix. Some of these interactions with other food components can be avoided by coating the iron form with hydrogenated oils or ethyl cellulose. Electrolytic iron has also been used for its increased bioavailability.

Legislation Concerning Cereal Fortification

Although cereal fortification can be an effective means of improving micronutrient status, there are some barriers to the general implementation. These include concerns related to a proliferation of the fortified foods if the fortification is voluntarily practiced by manufacturers, which would lead to a simultaneous replacement of the nonfortified foods in the diet. The success of fortification programs always depends on good control, so they should be set up, regulated, and enforced by the national governments. An uncontrolled food fortification program could result in excessive intakes of certain nutrients creating nutrient imbalances, and in consequence representing a risk to the health of consumers.

The addition of nutrients is generally practiced by manufacturers either voluntarily or because it is compulsory under national rules. In general, vitamins and minerals may be added in conformity with the legislation of the country in which the product is being sold. The Economic and Social Department of FAO has elaborated a review about the legislation status concerning rice and wheat flour fortification (Tables 4 and 5).

Table 4 Summary of voluntary and mandatory fortification of rice

Country	*Law status*	*Legislation*	*Known nutrient deficiencies*
Angola		No	Vit. A, I, Fe
Australia	Prohibited		
Canada	Voluntary	B_1, B_3	
Costa Rica	Voluntary	No	I, Fe
Cuba	Voluntary	No	Fe, Vits. B_1, C, A

Venezuela	Mandatory	B_1, B_2, B_3			+			

Rice fortification is voluntary in USA; however, most of the rice sold is fortified, and a recent regulation requires that rice to which folic acid has been added be labeled as enriched rice. In Canada, fortification of rice is also voluntary, and when labeled as enriched, it has added vitamin B_1, vitamin B_3, and iron. Moreover, in Canada the addition of vitamins B_5 and B_6, and folic acid is optional. Fortification of rice in Philippines has a long tradition, and there is a mandatory regulation for the addition of vitamin B_1.

There are currently 14 countries with legislations or regulations that mandate the fortification of wheat flour, whereas in countries such as Finland, New Zealand, and Norway law prohibits the addition of nutrients to wheat flour. In United States, the Food and Drug Administration approves the supplementation of four B-vitamins (thiamine, niacin, riboflavin, and folic acid) and iron to the wheat flour, obtaining "enriched flour," although this practice is regulated by Federal law. Recently, the USA government has passed a mandatory regulation concerning folic acid fortification. In the United Kingdom, it is required by law that the nutrients removed with the bran during milling be replaced in all types of flours, with the exception of whole meal. In addition, white and brown flour must have thiamine, niacin, iron, and calcium. From 1997, the Organización Panamericana de la Salud (OPS) is supporting the supplementation of iron to wheat flour due to its low cost and extensive consumption. In the previous years, different countries from South and Central America have implemented this measure for reducing the incidence of iron-deficient anemia. The levels of nutrients to be added are also regulated by national governments.

Future Prospects

Currently, in the developed countries the term "functional foods" or "nutraceuticals" seems to be old-fashioned, and the cereal-based products surely may be one of the best carriers of different compounds related to physiological functions. Therefore, the near future in nutrition could be the use of cereal-based products as carriers of ω-fatty acids and probiotic compounds such as fructo-oligosaccharides, inulin, etc.

FUEL ALCOHOL PRODUCTION

C C Maningat and S D Bassi, MGP Ingredients Inc, Atchison, KS, USA

Introduction

The production of ethanol or ethyl alcohol ranks among one of the oldest technologies starting with fruit and honey, and finally grain as fermentation media. Several centuries later, sugar cane, corn dry milling, corn wet milling, and ethylene are playing dominant roles in alcohol production.

The production of ethanol by the US corn refining industry began before the Second World War. It was used as a processing aid in the manufacture of rubber and as a fuel extender. After the war, the necessity of producing ethanol faded, but it got its first boost as a gasoline extender during the oil embargo of the 1970s when it offered a more economical alternative to high oil prices. Thus, fuel alcohol began as "gasohol," a popular gasoline extender during this period of oil shortage. Later when oil prices dropped, it helped fuel companies solve an environmental problem by replacing lead as an octane-enhancing fuel ingredient. In recent years, as urban centers struggle to achieve cleaner air, ethanol serves as a fuel oxygenate to control carbon monoxide problems and as an additive in reformulated gasoline to reduce smog-forming emissions. This article summarizes world ethanol production data, production processes, and ethanol's enhanced and diverse utilization in the fuel industry.

Global Ethanol Production Statistics

Ethanol is considered by far the largest fermentation end use worldwide. Global ethanol production increased from 28.7 billion liters (7.6 billion gallons) in 1993 to 33.3 billion liters (8.8 billion gallons) in 1998. Brazil accounted for most of the increase in production, with the US showing an erratic trend and EU's production remaining static in recent years. Table 1 shows that Brazil is the largest producer with 49% of global output followed by the United States (17%), China (8%), and European Union (7%).

Ethanol Production in Brazil

Brazil has the largest bio-ethanol industry worldwide. It began its fuel ethanol program in 1975. In the mid-1980s, ~75% of all the new cars sold ran on pure ethanol. Like the US, its growth in ethanol production has been driven by government policy aimed at reducing national dependence on oil and also at supporting farm incomes.

Ethanol is produced directly from sugar cane juice as well as from molasses that are a by-product of sugar processing. Brazil's choice of sugar cane as feedstock is likely to be copied by other countries like India, Thailand, and possibly Mexico. One of the significant changes in Brazil is the liberalization by the government of its domestic alcohol market, which followed the earlier liberalization of the sugar sector. The sugar cane industry consists of ~250 mills. About one-third of those mills produce only ethanol, and nearly all of the remaining mills can process both sugar and ethanol. There is considerable flexibility among the mills to produce either sugar or ethanol, depending on the relative return from these two commodities. Alcohol demand has been relatively flat in recent years due to gradual scrapping of vehicles powered solely by alcohol. All petrol sold still contains 26% ethanol, a mixture on which standard petrol engines can run without adaptation.

US Ethanol Production

Ethanol production in the US received a major boost in 1990 with the passage of the Clean Air Act Amendments providing for the establishment of oxygenated fuel program and reformulated gasoline program in an attempt to control carbon monoxide and ground-level ozone problems. Both programs require certain oxygen levels in gasoline: 2.7% by weight for oxygenated fuel and 2.0% by weight for reformulated

gasoline. Combined ethanol demand in 2000 for reformulated gasoline and oxygenated fuel programs was estimated at 650 million gallons per year.

Seventy-four ethanol manufacturing plants with yearly capacity of 10.2 billion liters (2.7 billion gallons) of ethanol used diverse feedstocks during production with corn being the dominant feedstock (Table 2). Majority of ethanol is produced in Illinois, Indiana, Iowa, Kansas, Minnesota, and Nebraska. About 90% of ethanol output is derived from corn. Several new plants opened in 2003 bringing the yearly production capacity to 3.7 billion gallons. The US ethanol industry is expanding, boosted by the growth prospects for cleaner burning fuels.

About 690 million bushels of corn in 2001 were processed to produce ethanol (Table 3). The amount of corn utilization for ethanol production increased from 1991 to 1994, and then dipped in 1995. Since then, the amount of corn usage has been increasing steadily from a low of 396 million bushels to a high of 690 million bushels.

EU Ethanol Production

The total ethanol output in EU was ~2.3 billion liters (608 million gallons) in 1997. France was the single largest producer followed by Germany and the United Kingdom. In France, ethanol is produced by fermentation of sugar beet and wheat. Ethylene-derived ethanol is also available from these three EU countries. In Italy, Spain, and Portugal, a substantial amount of alcohol is produced from distillation of surplus wine.

The Fuel Ethanol Industry

To produce fuel-grade ethanol, anhydrous ethanol is denatured in accordance with the regulations of the US Bureau of Alcohol, Tobacco, and Firearms. Typical denaturants are unleaded gasoline or natural gasoline. The minimum denaturant level is 2 gallons for every 100 gallons of ethanol. Since the denaturant is less expensive than ethanol, the maximum permitted level of 5 gallons of denaturant are typically added for every 100 gallons of ethanol. Specifications for denatured fuel ethanol are defined in ASTM D 4806 (Table 4). In the US, fuel-grade ethanol is currently blended into conventional gasoline, reformulated gasoline, and suboctane gasoline with the most common blend level being 10% v/v ethanol. Blends of 5.7% v/v ethanol (equating to 2% by wt. of oxygen) and 7.7% v/v (equating to 2.7% by wt. of oxygen) are produced to achieve regulatory compliance levels. At 10% v/v blend level, ethanol is usually added to 87 octane regular to make a mid-grade product, and to a mixture of 87 octane regular and 92 octane premium to make a premium product. When ethanol is blended to suboctane gasoline with 84 or 84.5 octane, the finished blend is 87 octane.

Table 4 ASTM D 4806 standard specification for denatured fuel ethanol for blending with gasoline for use as automotive spark-ignition engine fuel

Ethanol, vol.%, min.	92.1

Acidity (as acetic acid CH_3COOH) max, mass% (mg l^{-1})	0.007 (56)
pHe	6.5–9.0
Appearance	Visibly free of suspended or precipitated contaminants (clear and bright)

Ethanol is sold as an oxygenate or high-octane fuel that delivers improved vehicle performance and reduced engine knock while reducing harmful emissions and improving air quality. It is used to replace the fuel oxygenate, methyl tertiary butyl ether, which is being phased out as it is known to cause ground and surface water contamination and is resistant to microbial degradation. Ethanol is nontoxic and is quickly biodegradable in surface water, ground water, and soil. It contains 35% oxygen, and adding it as an oxygenate to gasoline improves the efficiency of fuel combustion resulting in reduced tailpipe emissions of volatile organic compounds and fine particulates that pose a health threat to humans.

Ethanol dramatically reduces carbon monoxide emissions, which are responsible for as much as 20% of urban smogs. It also reduces greenhouse gases emitted from vehicles, including carbon dioxide, methane, and other gases that contribute to global warming. A full-cycle analysis by the US Argonne National Laboratory concluded that per gallon of ethanol used in E-10 fuel (10% v/v blend of ethanol with gasoline) reduces greenhouse gas emissions by 12–19%, petroleum use by 90–93%, and fossil energy use by 40%. Ethanol serves as an excellent fuel additive in reducing pollution from off-road vehicles, such as motorcycles, all-terrain vehicles, and snowmobiles, which lack pollution control devices. As an alternative fuel, ethanol reduces a country's reliance on imported crude oil and gasoline, provides new market and adds value to agricultural feedstocks, and promotes rural development.

In addition to the traditional use of ethanol as a low level blend component in conventional or reformulated gasoline, other possible transportation fuel uses of ethanol like E-85, oxydiesel, aviation fuel, and fuel cells have varying degrees of potential. The term E-85 is used to denote fuels containing 75–85% v/v of denatured ethanol, with the remainder of the blend comprised of either conventional or reformulated gasoline, which is in the early stages of commercialization. Currently, the highest profile alternative fuel use for ethanol is the use of E-85 in flexible fuel vehicles. Per gallon use of ethanol in E-85 fuel reduces greenhouse gas emissions by 17–24%, petroleum use by 92–95%, and fossil energy use by 44%.

Oxydiesel is in the experimental or demonstration phase. It consists of a blend of traditional diesel fuel blended with up to 15% denatured fuel-grade ethanol and special additives. It can be used in existing diesel engines without modification. In a truck demonstration test performed in 1998, the performance characteristics of oxydiesel were very similar to No. 2 diesel.

Ethanol's application in aviation fuel has been examined with primary focus on piston-powered aircraft (spark ignition/internal combustion), but minimal amount of work has been done on turbine-powered aircraft (jet engines). Recently, an aviation-grade E-85 (AGE 85) has been developed. AGE 85 has 88% ethanol, and was certified by US Federal Aviation Administration for use in Cessna 180 and Cessna 182 engine-airframe combinations.

Ethanol, which contains 13% hydrogen, also has applications in fuel cells. Fuel cells work by combining hydrogen and oxygen in a chemical reaction to create electricity, without the noise and pollution of internal combustion engines. In principle, a fuel cell operates like a battery, but unlike a battery a fuel cell does not run down or require recharging. As long as fuel is supplied, it will produce energy in the form of electricity and heat with low emissions, which primarily consist of water and steam. Because ethanol has relatively simple molecular structure and is easy to transport and store, it lends itself to fuel reforming (i.e., the chemical process for extracting hydrogen from fuel) with relative ease. The primary benefits that ethanol provides in fuel cells include the following: liquids with high-energy density store well in vehicles; delivery through existing fuel infrastructure; less toxic than methanol and gasoline; does not pose a threat to the environment in the event of a spill; easier to reform than gasoline, hydrocarbons, and most alternative fuel options; reduction in greenhouse gas emissions; and reduced reliance on imported fossil fuel energy.

Feedstocks

Unlike any other liquid fuel alternative, ethanol is derived from a wide range of renewable feedstocks by fermentation technology. The major carbohydrate sources for ethanol fermentation are: (1) simple sugars from sugar cane, molasses, sugar beet, sweet sorghum, fodder beets, and fruits; (2) inulin, a fructose polymer, from Jerusalem artichoke, dahlia, and chicory; (3) starch from cereal grains (corn, milo, wheat, rye, sorghum, barley, triticale, and rice) and tubers (potatoes, sweet potatoes, and cassava); (4) cellulosic plant materials from wood, crop residues (corn stover, coconut husk, and wheat straw), and forages (alfalfa and sudan grass); and (5) by-product carbohydrates from food processing (whey, cannery waste, vegetable waste, sugar cane bagasse, and fruit waste) and paper production (waste sulfite liquor, wood waste, and pulp mill waste). The predominant feedstock is corn in the US and sugar cane in Brazil, but many agricultural crops, by-products, or process waste have been sourced for fermentable carbohydrates (Tables 2 and 5). The US, China, EU, Brazil, and Mexico are the top five corn-producing countries in the world (Table 6) (*see* **Grain Production and**

Consumption: Overview). Of the roughly 23 billion bushels of corn produced in the world, 9.5 billion bushels representing 41% of total was produced in the US. The share of China, EU, Brazil, and Mexico represents 19%, 7%, 6%, and 3% of the world's total corn production, respectively.

Ethanol can also be manufactured from ethylene, a petroleum-derived chemical, via synthesis. The manufacturing process consists of combining ethylene with water vapor at elevated temperature and pressure, and passing over the surface of a catalyst support impregnated with phosphoric acid.

Conversion of Feedstocks to Sugars

To produce monomeric, fermentable sugars, starchy feedstocks undergo a traditional cooking process to gelatinize the starch followed by liquefaction with α-amylase and saccharification with glucoamylase. The efficiency of liquefaction is a function of temperature, residence time, rate of heat-up, uniformity of heat distribution, and the amount and heat stability of liquefying enzyme. Saccharification depends on enzyme level, pH, temperature, and residence time. Modifications of the process evolved with respect to choice of processing conditions appropriate to a particular plant facility. Other technologies have emerged in succeeding years. For example, sulfuric acid hydrolysis of starch wastes was practiced in a potato chips industry. Another technology is steam explosion pretreatment of potato at high pressure, which hydrolyzed it into low-molecular-weight liquid starch.

Cellulosic feedstocks require a more elaborate conversion process to generate fermentable sugars, and more often would involve pretreatment processes because of the intractable nature of the raw material. Some of these pretreatment processes involve ammonia-fiber explosion, steam explosion, supercritical carbon dioxide explosion, ultrasonic, acid-catalyzed steam, and alkaline hydrogen peroxide. Primarily, the processes are designed to enhance the susceptibility of treated feedstocks to enzymatic hydrolysis, thereby increasing the yield of fermentable sugars. Typical technological applications in diverse cellulosic materials include ammonia-fiber explosion of corn fiber; steam explosion or alkaline hydrogen peroxide treatments of sugar cane bagasse; supercritical carbon dioxide explosion of sugar cane bagasse and recycled paper mix; and ultrasonic and acid-catalyzed steam treatments of waste office paper.

Fermentation Processes

Yeasts (*Saccharomyces cerevisiae*) are facultative anaerobes, which can ferment (*see* **Fermentation**: Origins and Applications) industrial sugars derived from any feedstocks (e.g., starch, cellulose, inulin, or sugars) to produce alcohol even in the presence of small amount of oxygen in the mash. The mash is fermented under anaerobic conditions except for the initial small amount of air present during the inoculation step. Fermentation of simple sugars by yeast goes through four characteristic phases: (1) the lag phase when the yeast cells become acclimated to their new environment; (2) the exponential growth phase when the yeast cells propagate rapidly; (3) the stationary phase; and (4) the death phase when alcohol

concentration is high and available sugar for yeast metabolism is low.

Yeasts use the glycolytic or Embden–Meyerhof pathway to break down sugars into energy, several intermediates which the yeast requires for cell growth, and large amounts of the major end products, ethanol and carbon dioxide, which the cell excretes. The efficiency to produce ethanol is influenced by the strain of yeast, pH, temperature, sugar concentration, nutrients, and microbial infection. The theoretical yield of ethanol can be calculated using stoichiometry. Every 1000 pounds of glucose (originating from hydrolysis of 901 pounds of starch) fermented by yeast produce 511 pounds of ethanol and 489 pounds of carbon dioxide. Thus, the yield of ethanol based on glucose is 51.1% (w/w) and, if calculated based on starch, the yield of ethanol is 56.7% (w/w). Actual yields of ethanol are generally slightly lower than the theoretical yield because ~5% of the sugar is utilized by the yeast to produce new yeast cells and minor products such as glycerol, acetic acid, lactic acid, and fusel oils. Fermentation efficiency can be expressed as the ratio of the actual weight of alcohol produced and the theoretical weight of alcohol produced from glucose multiplied by 100.

The production of ethanol from grain feedstock involves two processes: dry milling and wet milling. In dry milling (*see* **Maize**: Dry Milling), the entire kernel from corn or other grains is first ground into flour (meal) and slurried with water to form the mash. The mash is processed in a high-temperature cooker, cooled and treated with liquefying and saccharifying enzymes to convert starch to glucose. The converted mash is further cooled and transferred to batch fermenters where yeast is pitched. For continuous fermenters, the time of enzyme and yeast addition is adjusted for a simultaneous saccharification and fermentation process. Fermentation of glucose to ethanol and carbon dioxide begins, and generally takes ~40–50 h to complete. After fermentation, ethanol is stripped from the beer, and the remaining stillage is centrifuged to separate the coarse grain from the solubles. Concentration of the solubles by evaporation yields the syrup or condensed distillers solubles, and co-drying of the coarse grain and syrup yields the dried distillers grains with solubles. The ethanol stream is concentrated to 190 proof by distillation and then dehydrated to 200 proof by ternary azeotropic distillation or by molecular sieve technology.

In wet milling (*see* **Maize**: Wet Milling), the kernel of corn is steeped in water containing dilute sulfurous acid for 24–48 h. The steeped kernels are ground to separate the germ. The remaining fiber, gluten, and starch components are separated using centrifuges, screens, and hydrocyclones. Steeped liquor is concentrated by evaporation, and co-dried with the fiber component to yield corn gluten feed. The gluten component is filtered and then dried to produce corn gluten meal. The fermentation of starch slurry to ethanol is conducted similarly as the dry milling process described above with respect to cooking, enzyme conversion, and yeast fermentation. Current corn wet-milling technology produces 2.5 gallons of ethanol per bushel of corn, while dry-milling technology produces 2.7 gallons of ethanol per bushel of corn. Increased fermenter capacity and reduced production cost can be realized by recovering corn fiber ("quick fiber process") and germ ("quick germ process") before fermentation.

One method to achieve increased production of ethanol without building new facilities is through the adoption of high gravity fermentation. In the fuel alcohol industry, normal gravity mash concentrations between 20 and 24 g dissolved solids per 100 g of mash are fermented to produce ethanol ranging from 9% to 12% v/v. Mash concentrations ranging from 25 to 38 g dissolved solids per 100 g of mash are termed very high gravity, and during fermentation can yield as high as 24% v/v ethanol. The technology of very high gravity fermentation had been employed in the production of fuel alcohol using barley, oat, wheat, rye, or triticate as feedstock. The benefits of very high gravity fermentation technology include: considerable saving of water; reduced distillation costs; reduced capital costs; lower energy cost per liter of alcohol; reduced risk of bacterial contamination; and higher ethanol production with a given plant capacity and labor costs.

Biomass Fermentation

Cheap and renewable feedstocks for ethanol production are readily available worldwide, in the vast quantities of agricultural residues (biomass). Using waste plant materials such as corn stover, coconut husks, wheat straw, or wood waste as a renewable energy source makes good sense. For example, waste disposal problems may be converted into profits as ethanol or other products. Disposal costs in landfill or as sewage are reduced. In addition, it is a solution to air pollution problems in some areas that are sensitive to clearing of harvested fields by burning.

The potential yield of ethanol in liters/hectare/year from cellulosic biomass ranks second to sugar cane, but higher than sweet sorghum and corn. Biomass contains cellulose, hemicellulose, and lignin, which pose difficult challenges during fermentation into alcohol. Hydrolysis yields not only six-carbon sugars (hexoses), but also five-carbon sugars (pentoses) that are not readily fermented by yeast to alcohol.

A Canadian company developed the bioethanol process, which has advanced technology to produce ethanol from biomass. The bioethanol process involves pretreating plant fibers, enzyme hydrolysis, fermentation, and alcohol distillation. The yield of ethanol is $\sim 300\,\mathrm{lt}^{-1}$ of fiber.

Microorganisms from several species are capable of transforming cellulosic feedstocks from different sources into ethanol. Recombinant *Klebsiella oxytoca* strain P2 was utilized in simultaneous saccharification and fermentation of acid-treated bagasse to yield ethanol. The same *Klebsiella* strain produced ethanol by fermentation of sugar beet pulp. Commercial feasibility of ethanol production from bagasse is possible using cellulase from mutant strains of *Trichoderma reesei* and continuous fermentation with immobilized *Saccharomyces cerevisiae* AD-3. *Pichia stipitis* CBS 5773 and a genetically engineered xylose-fermenting yeast produced ethanol from bagasse hydrolyzates.

Thermophilic strain of *Bacillus stearothermophilus* fermented lignocellulosic wastes from wheat straw and sugar cane bagasse into ethanol under anaerobic conditions. Some species of anaerobic and thermophilic *Clostridium* can also ferment plant wastes from sugar cane bagasse, corn stover, and forestry residues into ethanol. Fermentation of bagasse, corn stover, and corn hulls plus fiber by genetically engineered *Escherichia coli* strain KO 11 was substantially complete within 48 h. Genetically engineered *E. coli* KO 11, *E. coli* SL 40, *E. coli* FBR 3, *Zymomonas mobilis* CP 4 (pZB 5), and *S. cerevisiae* 1400 (pLNH 32) fermented hydrolyzates of corn fiber to ethanol. Other feedstocks such as rice hull and mixed-waste office paper were also successfully fermented by recombinant *E. coli* KO 11.

Pentose Sugar Fermentation

One of the drawbacks of fermenting waste cellulosic materials is the inability of common fermentative organisms to utilize pentose sugars such as xylose and arabinose. Mainly fungi and nontraditional yeasts are capable of fermenting pentose sugars to ethanol. *Rhizopus* strains have the ability to ferment glucose, xylose, and arabinose as well as complex substrates such as cellulose, oat-spelt xylan, corn fiber, and corn germ pressing. A cellulytic fungus, *Aspergillus terreus*, was able to ferment glucose and other hexoses, pentoses, and disaccharides to ethanol. Two fungi, *Candida entomaea* NRRL Y-7785 and *Pichia guilliermondii* NRRL Y-2075, preferentially utilized glucose > xylose > arabinose from mixed substrates and produced ethanol, xylitol, and arabitol. Using a mixture of glucose, xylose, and arabinose in ratios typical of corn fiber hydrolyzates, cultures of *Pichia guilliermondii* strain NRRL Y-12723 preferentially utilized glucose and only slowly metabolized xylose and arabinose.

Candida auringiensis, Candida succiphila, Ambrosiozyma monospora, and *Candida* species YB-2248 have the ability to ferment arabinose to ethanol. These yeasts can also ferment xylose. Nontraditional yeasts, *Candida shehatae, Pachysolen tannophilus,* and *Pichia stipitis*, fermented a mixture of glucose and xylose to produce ethanol. Organic nitrogen sources enhanced ethanol and xylitol production from xylose during fermentation by *Candida shehatae* ATCC 22984. *Pachysolen tannophilus* immobilized in calcium alginate beads fermented xylose to ethanol on a continuous basis. The yeast *Candida peltata* NRRL Y-6888 preferentially utilized glucose > xylose > arabinose from mixed substrates.

The yeast *Pichia stipitis* NRRL Y-7124 has the ability to ferment xylose to 76% of theoretical ethanol yield. Lignocellulose hydrolyzates containing xylose and glucose provided good substrates for ethanol production by *Pachysolen tannophilus* NRRL Y-2460 and *S. cerevisiae* NRRL Y-2235. A fermentation process produced ethanol from pretreated biomass comprising xylose and cellulose using cellulase, β-glucosidase, xylose isomerase, and *Saccharomyces pombe* ATCC No. 2476.

E. coli KO 11 was reported to be capable of fermenting xylose into ethanol. Mutants of *E. coli* KO 11 have been used to ferment arabinose and xylose to ethanol selectively in the presence of high concentrations of glucose. Two hyperproductive strains of the mutants retained the ability to metabolize all three sugars with faster fermentation and higher alcohol yields than KO 11. A novel ethanologenic *E. coli* strain FBR3 acts as biocatalyst for converting lignocellulosic hydrolysates containing mixed sugars (e.g., arabinose, xylose, and glucose) into ethanol.

Genetic engineering played a significant role in overcoming the inability of common microorganisms to ferment pentose sugars. *S. cerevisiae* strain 1400 (pLNH 32) has been genetically engineered to ferment xylose. This recombinant strain fermented a mixture of glucose, xylose, arabinose, and galactose into ethanol at 90% yield in 24 h. Another recombinant organism, *Klebsiella oxytoca* strain P2, has the ability to ferment mixed sugars in which sugar utilization is in the order of glucose > arabinose > xylose and ethanol production is in the order of xylose > glucose > arabinose. Recombinant strains of *Klebsiella oxytoca* and *E. coli* can ferment pentose sugars to ethanol with high selectivity and at reasonable ethanol concentration and fermentation time. Hydrolyzates of corn hulls and germ meal containing mixed sugars (e.g., arabinose, glucose, and xylose)

were fermented into ethanol using recombinant *E. coli* strains KO 11 and SL 40.

Whey Fermentation

Whey is the lactose-rich, watery liquid remaining after the curd is formed in the manufacture of fermented or acidified dairy products such as cheese. Liquid whey generally contains 4.8% lactose, 0.6% protein, 0.6% salts, 0.05% fat, and the balance being water. Spray-dried whey has 3.5–5% moisture, 11–14.5% protein, 0.5–1.5% fat, 9.8–12.3% ash, and 61–75% lactose. Many dairy companies have to contend with the utilization or disposal of liquid whey as a by-product in the process. Ethanol production is one possible avenue by utilizing whey as a feedstock for fermentation.

Lactose, a disaccharide, present in whey can be hydrolyzed by lactase enzyme into galactose and glucose. Normal distillers yeast (*S. cerevisiae*) preferentially ferments glucose first, and then slowly ferments galactose into alcohol. Some strains of yeast, e.g., *Kluyveromyces marxianus*, variety *marxianus* (previously known as *Kluyveromyces fragilis*), can ferment lactose without prior hydrolysis. Several strains of yeast belonging to *Kluyveromyces marxianus*, *Kluyveromyces lactic*, *Candida pseudotropicalis*, *Candida versatilis*, and *Trichosporon melibiosaceum* have reasonable yield of ethanol during batch fermentation of lactose. Ethanol was also produced by transformed strains of *S. cerevisiae* acting on whey or by recombinant flocculating *S. cerevisiae* expressing the genes of *Kluyveromyces marxianus* coding for β-galactosidase and lactose permease acting on cheese whey permeate.

Maximum ethanol yield is achieved by batch fermentation of cheese whey or continuous anaerobic fermentation of whey by *Candida pseudotropicalis*. In a small cheese plant, whey waste fermentation with *C. pseudotropicalis* ATCC 8619 resulted in daily production of 720 l of 190 proof alcohol and 40 kg of *Candida* yeast from 25 000 l of whey.

Cofermenting food processing wastes with cheese whey, which acted as a wetting agent and provided macro- and micronutrients for the yeast, resulted in increase in alcohol yield and decreased fermentation time. These advantages were also attained in another co-fermentation process involving whey permeate from the dairy industry and starchy waste from the potato industry treated with a mixed yeast inoculum of *Kluyveromyces fragilis* and *Schizosaccharomyces pombe*. Simularly, liquid whey supplemented with corn and the saccharified mash fermented with a mixed yeast inoculum of *Kluyveromyces fragilis* and *Saccharomyces cerevisiae* improved the yield of ethanol.

Table 7 HPLC analysis of fermentation liquor of a 60 h mash from a dry corn milling/milo/wheat starch continuous fermentation process

Component	*Retention time (min)*	*Amount*[a] *(g l^{-1})*
Maltotetraose	7.9	14.4
Maltotriose	8.6	0.9
Maltose	9.6	3.0
Citric acid	10.8	0.7
Glucose	11.2	3.3
Fructose	12.2	0.4
Succinic acid	15.1	0.4
Lactic acid	16.2	4.6
Glycerol	16.8	6.8
Acetic acid	18.9	0.6
Methanol	23.1	2.2
Ethanol	25.6	12.0

[a] Units are in g l^{-1} except for ethanol, which is in vol.%.

Monitoring Progress of Fermentation

Conventional high-performance liquid chromatography (HPLC) procedures are used to track the progress of fermentation by analyzing mash composition. A typical chromatographic result is shown in Table 7, where fermentation liquor of a 60 h mash from a dry corn milling/milo/wheat starch continuous fermentation process is assayed using a Waters HPLC Model 515 pump equipped with an autosampler and a refractive index detector. Separation of components is accomplished using Bio-Rad's Aminex HPX-87H column and 5 mM H_2SO_4 eluent operating isocratically at 60°C. Ethanol is the major component with minor or trace amounts of methanol, glycerol, lactic acid, acetic acid, succinic acid, citric acid, maltotetraose, maltotriose, maltose, fructose, and glucose.

A fully automated system can also be used for online monitoring of ethanol in fermentation liquor. In this system, ethanol is determined on precleaned filtrate by liquid chromatography on a reversed-phase column and amperometric detection with a biosensor consisting of a carbon-paste electrode modified with co-immobilized horseradish peroxidase and alcohol oxidase. Biosensors based on amperometry and constructed using immobilized cells of either *Gluconobacter oxydans* or *Pichia methanolica* also provide accurate estimates of glucose and ethanol in mixtures.

Another type of monitoring equipment includes an automated glucose analyzer modified to form a multichannel flow-injection analysis system for the sequential determination of glucose, ethanol, and glutamate. The system is equipped with a mini-reactor column containing immobilized glucose oxidase, alcohol oxidase, or glutamate oxidase. By comparison, another flow-injection analysis setup employs a reagentless alcohol dehydrogenase working

electrode, a platinum auxiliary electrode, and an Ag/AgCl reference electrode.

Distillation Processes

A simple distillation column to separate an ideal, binary mixture contains several elements. These elements consist of the feed (which contains the two components to be separated), the source of energy (primarily steam to drive the process), the overhead product (consisting primarily of the feed component with the lower boiling point), the bottoms product (containing the feed component with higher boiling point), and the condenser (which transforms and splits the vapor into a liquid (reflux) and an overhead product).

If the ethanol–water mixture is an ideal one, the distillation system described above would be able to separate the beer feed into a relatively pure ethanol overhead product and a bottoms product of stillage free of ethanol. However, the ethanol–water mixture in the beer feed is not an ideal system. Distillation of an ethanol–water mixture follows the vapor/liquid equilibrium diagram, in which a point is reached where the vapor boiling off of the liquid is of identical composition as the liquid from which it is being evolved. What is formed is a constant boiling mixture or an azeotrope with 95% ethanol content. To produce pure ethanol, the simple distillation process is modified, and the vapor/liquid information is divided into three distinct zones of process and equipment requirements namely stripping, rectifying, and dehydration.

Efficient distillation processes (*see* **Beverages**: Distilled) have been in commercial operation for many years for the production of high-grade, 190 proof ethanol. After fermentation the beer feed is preheated using recovered heat from effluent streams and vapors in the process. The preheated beer is degassed and pumped to the beer still equipped with stripping trays below and above the feed point. Condensed vapors from the top of the column are fed to the extractive-distillation column, which removed the impurities as overhead product to be condensed as a low-grade ethanol. The purified, diluted ethanol from the bottom of the column is pumped to the rectifying column, which has an integral stripping section. The high-grade ethanol product is taken as a side draw from one of the upper trays of the rectifying column. Fusel oils are drawn off below the product draw tray to avoid buildup of these impurities in the rectifying column. Fusel-oil draws and overhead "heads" cut are sent to the concentrating column to recover ethanol, which is fed back to the extractive-distillation column for re-purification and recovery of ethanol.

Anhydrous Ethanol Production

To produce anhydrous ethanol, a dehydrating column and an entrainer recovery column are put in operation. The entrainer used to remove water as a ternary azeotrope may be either benzene, heptane, cyclohexane, n-pentane, or diethyl ether. The three-component azeotrope boils at a lower temperature than any of the components, and passes overhead from the column, carrying the water upward. In this process, the alcohol feed enters the dehydrating column near the top, and comes in contact with the entrainer. In this section of the column, the three-component mixture seeks to form its azeotrope, but is deficient in water and contains more ethanol than the azeotrope composition. This excess ethanol is rejected downward in the liquid, and is withdrawn as an anhydrous product from the bottom of the column. On the other hand, the water joins the entrainer, passing upward as vapor to form a mixture that is near the ternary azeotrope composition. The condensed mixture separates into two layers in the decanter, and the entrainer-rich layer is refluxed from the decanter back to the top of the dehydrating column. The aqueous layer is pumped to the entrainer-recovery column, in which the entrainer and ethanol are concentrated overhead and the stripped water emerges from the base.

Significant improvements in the above processes were implemented to achieve maximum recovery during the production of motor fuel-grade ethanol. Fermented beer is preheated in a multistage heat exchanger employing a "boot-strapping" operation which picks up heat from the dehydrating system, rectifying column, and hot stillage. The preheated beer is degassed to remove residual carbon dioxide before entering the pressurized beer column. Heat is provided to the beer column by steam through a forced-circulation reboiler. The ethanol stripped from the beer in the lower part of the column is rectified to 95% concentration, and is taken as a side draw a few trays below the top of the rectifying section. The condensed overhead vapors are refluxed to the top of the beer column, with a small draw of "heads" taken to avoid accumulation of congeners. Fusel-oil draws are also taken from the rectifying section of the beer column into the decanter. The 95% ethanol enters the dehydrating column for anhydrous ethanol production according to the process described previously.

Ternary azeotropic distillation for anhydrous ethanol production is being supplanted with molecular sieve dehydration utilizing pressure-swing adsorption technology. Molecular sieves are manufactured from potassium aluminosilicates, and are described as hard, granular substance with spherical or cylindrical shape.

The typical sieve used in ethanol dehydration has an average diameter of the interstitial passageway of 3 Å. The separation of ethanol–water mixture is thus possible because the ethanol molecule has a mean diameter greater than 3 Å, and water molecule has a mean diameter less than 3 Å and can be adsorbed within the molecular sieve structure. The ethanol molecules are too large and pass out of the vessel leaving the water behind. Hot gas regeneration method was employed to displace the water from the molecular sieve beads. Physical deterioration of the beads occurred due to excessive thermal shock, especially for dehydration systems in the liquid phase. During the 1980s, vapor-phase, pressure-swing, vacuum-purge adsorption technology was applied to molecular sieve ethanol dehydration. This technology extended molecular-sieve bead life by a mild regeneration process using part of the recycled, superheated anhydrous ethanol vapor.

The adsorptive dehydration of aqueous ethanol in the gas or liquid phase has been conducted using carbon molecular sieves, which preferentially absorb water. The carbon molecular sieves have average effective pore diameter of 2.0–5.0 Å. Ground corn having operational temperature ranges between 80°C and 100°C has also been used as an adsorbent to remove water from ethanol vapors. The mechanism of adsorption is believed to involve transport of water molecules into the structure of adjacent starch granules immobilized on the surface of corn grit particles. Selectivity for water in a packed bed separation process with pure starches increases with increasing ratio of amylose to amylopectin. Corn grits treated with α-amylase have enhanced desiccant or water adsorption capacity useful in dehydrating aqueous ethanol.

RFA is the national trade association for the US ethanol industry working to secure a strong marketplace for ethanol. Its membership includes businesses, individuals, and organizations

involved in the production, blending, marketing, and promotion of ethanol. RFA serves as a link between the ethanol industry and the federal government to promote increased production and use of ethanol through supportive policies, regulations, and research and development iniatives.

http://www.ncga.com – The National Corn Growers Association (NCGA) with 32 000 members is the largest national nonprofit organization representing the interests of US corn growers. The national headquarter is located in St. Louis, MO with offices in Washington, DC. With the help of corn growers nationwide, NCGA defines the future of corn through research, market development, public policy, production, and education. It publishes "The World of Corn," an annual publication that reports US Department of Agriculture data on the production and consumption of corn in the US and around the world.

http://www.atcc.org – The American Type Culture Collection (ATCC) is a global nonprofit bioresource center that provides biological products, technical services, and educational programs to private industry, government, and academic organizations around the world. ATCC was established in 1925 when a committee of scientists recognized a need for a central collection of microorganisms that would serve scientists all over the world. Its headquarter and laboratory facilities are in Monassas, VA.

G

GENETICALLY MODIFIED GRAINS AND THE CONSUMER

J M Jones, College of St. Catherine, Arden Hills, MN, USA
C I M Jones, Minneapolis, MN, USA

Introduction

Consumer opinion about genetically modified (GM) grains and foods ranges from excitement to resolute fear. Somewhere in the middle lies the consumer majority. If consumers have heard of GM food, they have mostly heard contradictory snippets from Malthusian and humanitarian discourses calling for biotech solutions that could help feed the world to the apocalyptic sounding "Frankenfood," which like Mary Shelley's 1818 novel evokes the dangers associated in messing with nature's order. In the end, the ultimate success or failure of GM grains will not depend on laboratory or farm research successes, but on consumer acceptance. This article covers the following: (1) the range of world consumer opinion concerning GM grains and foods and (2) an assessment of the factors involved in forming those opinions.

Consumer Perception of GM Grains and Foods

Much of the world has never heard of GM foods or grains. Even in the best cases (developed nations that have active campaigns and education movements on both sides of the spectrum concerning GM foods), polls only show that 70% of consumers are familiar with GM foods. In many cases, the awareness and actual knowledge or willingness to learn more is much smaller (as low as 25% in some surveys). Table 1 gives some comparative data for some countries in Europe.

When consumers in the world hear of GM foods, their perception could be grossly summarized as wary. Of course, the spectrum of opinion varies drastically across geographical, economic, political, and social lines. Interestingly, both in the USA and Europe, consumers give lower acceptance ratings when asked about the genetic modification of foods than when asked the same question using the term "biotechnology."

The greatest advocates for GM foods generally come from the USA and a few other select countries. The scientific and governmental leaders in the USA believe that GM foods, when appropriately tested and used, could be a boon for the world in terms of food supply, environmental protection, and economic development. Consumer acceptance was slowly increasing until the Starlink debacle occurred. Starlink corn was approved for use in animal food. It was not approved for use in human food because regulators wanted further testing to ensure there were no allergy risks. Most consumers failed to understand this and assumed that the recall of the product meant it was unsafe rather than merely not receiving final approval. Now that the brouhaha has died down, there is again slowly growing acceptance.

The voices of Europe, led by France, take a more skeptical approach and possibly trade protectionist approach. Scientific and governmental leaders in Europe do not completely reject GM foods, but instead believe they have not been proven safe and therefore invoke "the precautionary principle." This helps protect their markets. Interestingly some countries are more accepting of GM crops than they are of the food. This seems to be somewhat contradictory (Table 2).

The opinions of the governments in the rest of the world fall somewhere in between those of USA and Europe, with data for developing nations still quite scarce. It is not surprising that consumer perception generally follows the advice of their scientific and political leaders. Thus, consumers in the USA are far more accepting of the idea of GM foods than the rest of the world.

Developing Nations

A 2000 study published in *Scientific American* shows that globally developing nations account for about

Table 1 Awareness and knowledge of biotechnology in selected countries in Europe

	% Who talk about it at least some	*% Who would read or view to learn more*	*Mean number of known applications*	*Knowledge (mean correct score out of 10)*	*% Engaged in the process*
Denmark	50	77	2.23	6.60	47
Finland	43	68	1.71	6.21	31
France	37	80	1.76	5.70	29

one-quarter of the area employed for GM crops. Proponents of GM foods usually cite the developing world as the greatest potential benefactor of GM foods, yet studies of what the people in developing countries think of GM foods are few are far between.

One of the great worries among GM food opponents is the potential to create further economic imbalance between the impoverished and wealthy countries. So while many developing nations look at GM food, especially grains, with a keen eye towards solving many health and hunger issues, many leaders in developing nations fear that GM food would not move their countries towards economic self-sufficiency.

In fact, in 2002, the African nation of Zambia rejected a deal proposed by the USA in which they would accept GM grain from the International Federation of the Red Cross. In a statement, the Zambian government said it would prefer its poor to die than to make the entire national food supply unhealthy. This shows the extent of pervading fear about this technology.

Leaders and scientists in South America seem a little more welcoming of GM food. Argentina, for example, is the second largest adapter by acreage of GM food crops in the world. In *Southern Voices: An Online Debate on Biotechnology and Food* conducted in 2001 by the Network University in The Netherlands, scientists and leaders from developing nations gave their opinions on biotechnology. Many Latin American nations (as well as other developing nations) were excited about the prospects of GM food, but favored a type of "open source" biotechnology, in which patent protection would not create a dependency on developed nations.

India To date, there has been no comprehensive study of how Indians feel about GM foods, but scientific and government officials are trying to jump start biotechnology in India. At the Bangalore Bio 2003 conference, a majority of Indian scientists came out in favor of GM foods, arguing that the number of infant deaths (61 out of every 1000 die from disease and hunger) could be reduced with GM foods. However, the scientists argued that GM foods should be researched, produced, and approved in India so they would not have to rely on the West for such technology. They argued that rich European nations have the luxury of choosing not to accept GM foods, but in countries like India the acceptance of biotechnology ends up as a choice between feeding and not feeding people.

Africa Similar to the resistance to GM food in Zambia, the governments of Zimbabwe, Mozambique and Botswana all initially protested the introduction of GM food crops into their countries, but eventually relented. However, African nations worry about GM foods. An international campaign is currently

underway in Malawi to reject 250 000 metric tons (t) of GM maize. The latest reports, however, indicate that most of the Malawian farmers have decided to ignore the warnings and plant the maize.

In a different development, in March 2003 South African consumers started a campaign for GM food labeling, indicating that consumers in South Africa are aware of GM foods and want the right to choose between eating them or not.

Pacific Nations

It may be stated that major nations on the Pacific, including Australia, New Zealand, Japan, China, and India provide a glimpse of the middle ground in this debate. Though varied in their opinions, these nations seem to be the moderates in the GM food debate – cautious, yet accepting. In countries like Australia and New Zealand, consumers seem evenly split in the debate over GM foods. And while no one is yet allowed to produce GM foods for public consumption in Australia and New Zealand, both countries are actively researching the production of biotech food crops.

Like in Europe, most governments in Asia have not given the go-ahead for GM food crop production, but according to a 21 February 2003 article in the *New York Times*, other major Asian countries, including Japan, Thailand, The Philippines, and Malaysia, have set aside billions of dollars for research on biotech crops. The same article reports that China is so far ahead in its research on GM food crops that it stands to dominate the region in agricultural production if GM food gains acceptance.

Australia A 2001 survey of Australian consumers conducted by the government agency, Biotechnology Australia, showed a growing acceptance of biotechnology, from 28% in 1999 to 35% in 2000 to 49% in 2001. The strongest acceptance among consumers was for GM foods that might induce health benefits (lower cholesterol, reduction in allergens etc.). The survey showed lowest consumer acceptance of foods engineered to ward off pests or improve taste.

Australian agencies are not totally convinced, however. In May 2003, despite the overall rise in acceptance for GM foods, Victoria, a southern Australian state, joined the rest of Australian canola producing states by halting the release of GM canola for at least another year. GM canola was to be Australia's first GM food crop.

New Zealand A 1999 study, conducted by HortResearch in collaboration with AgResearch, Forest Research Institute, Auckland University, and Massey University on New Zealanders' attitudes towards GM foods, found the country split in half between those that favored GM foods and those that opposed them. New Zealand also seems to show indications of a very polarized country, with 25% of the 908 responders having extreme negative feelings towards GM foods and 18% having very positive feelings towards them.

The study also showed some interesting demographic differences. Young (18–24 years) and male groups were the most likely to support GM foods, whereas older (35+ years) and female groups were more likely to oppose them. The study also indicated stronger approval for GM foods in urban over rural areas.

New Zealand's scientific, governmental, and agricultural communities are still very cautious over the use of GM grains or oilseeds. However, in May 2003, New Zealand joined a World Trade Organization (WTO) disputes case against the European Union (EU) because of its refusal to open markets to GM foods. This does not imply that New Zealand supports the production or trade of GM foods, but that the government believes in a trade system that sets health and environmental standards based on scientific evidence and risk analysis.

China In 2001, China implemented a strict labeling policy on GM soybeans. The reason given for the move was public outcry and safety. Some think the labeling requirement may have been less about public perception or fears, and more about economic protectionism.

China has halted the commercial production of biotech food crops that had already been approved due to opposition from major trade partners. Nevertheless, despite the labeling and export concerns, China remains the world's second largest spender on GM food research (US expenditure stands at $1.5 billion).

Japan Surveys in 2001 showed that Japanese consumers appear less ready to embrace GM foods than other Pacific nations. The Biotechnology Strategy Council, a government agency erected in July 2002, was partially conceived to fight this perceived problem. One of its primary goals is to educate the public about the issues surrounding biotechnology.

European Nations

A study conducted by the American Association for the Advancement of Science in 1999 looked at the difference between European and US perceptions over GM foods. A similar study, the Eurobarometer, conducted every two to three years (most recently in

2002 – "Europeans and biotechnology in 2002") by The European Commission breaks down the various European opinions on biotechnology issues. Both studies show a wide gulf between US and European acceptance of GM foods.

Seventy-one percent of the 16 500 consumers interviewed in EU countries for the Eurobarometer responded that they did not want to consume GM foods. This contrasts with a commonly quoted rate of ~70% acceptance rate by US consumers. While still in the minority, the Eurobarometer showed that European students, youth, higher income people, and men had a higher acceptance rate of GM foods, whereas, lower income people, the elderly, and women rejected GM foods at a much higher rate than the survey average.

EU candidate countries According to the Eurobarometer, candidate countries (Slovenia, Czech Republic, Slovakia, Turkey, Malta, Romania, Lithuania, Estonia, Hungary, and Cyprus) survey responses about attitudes to GM food reflect the opinions in the EU. Fifty-two percent of those queried in the candidate countries (compared to 56% in EU countries) viewed GM foods as dangerous.

Southern Europe (Italy, Greece, Portugal, and Spain) A study of 252 food shoppers in Modena, Italy during the Fall of 2001 conducted by Cal Poly State University in California showed that only 28% of the consumers queried in Italy knew what GM foods were. Only 43% of the shoppers queried said they would even consider purchasing GM foods.

The 2002 Eurobarometer showed that Greece was one of the four countries (France, Austria, and Luxembourg) that was particularly hostile to GM foods. In contrast, the 2002 Eurobarometer showed that Spain and Portugal were two of only four countries in Europe (joining Ireland and Finland) that showed overall support for GM foods.

British Isles England and Scotland share an overall disapproval for GM foods. In separate studies for the two countries in 2003 (Mori Environmental Research Bulletin and Public Perceptions of Food and Farming in Scotland), about 56% of consumers in each country were against GM foods, just slightly less than the rest of Europe. Only 14% of the English surveyed would themselves buy GM food products. Consumers in the Scottish survey stated they would neither buy food labeled as "GM," nor actively seek out additional information.

Ireland was more supportive of GM food. A majority of the consumers supported GM foods according to the 2002 Eurobarometer. However, a 2000 study by Cal Poly State University, showed a slight majority opposed GM foods. This either falls in the bounds of survey error or suggests a growing acceptance of GM foods.

Scandinavia (Finland, Denmark, Norway, Sweden, and The Netherlands) Among the EU countries, the Scandinavian countries are the most engaged in GM food research. While most Scandinavian countries still have a majority of consumers opposed to GM foods, consumers in the Scandinavian countries are the most supportive (as a group) of GM foods. The percentages are closer to an even split among the countries, compared to the 71% EU rejection average.

Western Europe (Germany and France) In France, a population particularly hostile towards GM foods, much of the public perception can be traced to two factors: first, France's age old traditions celebrating food as an important cultural placard; and second, a strong grassroots campaign against GM foods conducted by a series of well-received environmental, consumer, economic, and political organizations. Consumers in Germany do not go as far as the French, but a large majority of Germans align with the French on this issue.

North American Nations

North Americans are the greatest proponents for GM foods in the world, and consumers reflect the opinions' of scientists and leaders. Multiple surveys between 2001 and 2003 show a varying degree of public acceptance, from a low of 32% to a high of 71%. Even with the varying degree of sample results, most surveys do show a majority of Americans and Canadians support and accept GM foods. Caribbean consumers according to a 2001 survey were less accepting of GM foods and grains than their North American counterparts.

April 2003 studies conducted by the Universities of Calgary and Alberta show Canadian consumers support GM food (52%), but approval has declined over the past 6 years. The study also shows that more than half of consumers surveyed would buy GM foods if they were cheaper than nonmodified foods. Seventy-five percent of Canadians want all GM food to be clearly labeled.

According to surveys conducted in the USA, 70% have heard or read about biotechnology but there is a range of opinions about GM foods and grains. Like Canadians, over 85% of US consumers want these products labeled. US consumers respond with the greatest acceptance when queried about specific applications. For example, 75% of US consumers believe that GM grains can help solve world hunger

and world malnutrition. US consumers respond with more resistance when they are asked about their personal choices or beliefs. In a 2001 survey conducted by BIGresearch only 23% of respondents answered in the affirmative to questions of "Would you eat GM food products?" and "Is GM food safe to eat?" About half were undecided and about 30% answered in the negative. Furthermore, in a 2001 ABC News poll, 57% of US consumers said they would be less likely to purchase a product labeled GM.

Factors Influencing Consumer Perception

Social, economic, and political factors contribute to consumer opinions around GM grains. Understanding of each of these contributes to the success or failure of GM foods. Nine key factors contribute to consumer opinion about GM grains: use; scientific literacy; trust in regulatory organizations; labeling; safety (environmental and health); perception of benefit; price; religion; and global and socio-economic issues.

Use

The biggest factor when it comes to consumer perception is the understood use of biotechnology. Among uses for biotechnology, genetic modification for food and food grains usually falls somewhere in the middle of the spectrum in terms of acceptability, far below the acceptance of medical uses. Furthermore, consumers differentiate uses within the realm of GM grains. Consumers find GM grains that reduce allergens or pesticides far more appealing than GM foods providing better taste or nutrition. This also suggests that many surveys may have flaws if potential use remains unspecified.

Scientific Literacy

Another major factor in consumer acceptance of GM grains may be scientific literacy. Some surveys have shown that people who understand the concepts of DNA and gene splicing are more accepting of GM foods. However, a major 1999 study conducted by the American Association for the Advancement of Science, compared scientific and genome literacy in Europe and the USA. While the European consumer scored significantly higher compared to their US counterpart in terms of genome knowledge, they showed much greater mistrust of GM grains and foods.

Trust in Regulatory Organizations

European consumers also have greater mistrust for a large number of scientific and regulatory bodies that come out in favor of the safety of GM food. In a comparison of US and UK consumers, 76% of US consumers trusted the government's role "in securing the safety of general food supply." Only 48% of UK consumers felt that same way. The Eurobarometer showed similar feelings – only 32% of respondents felt that "public authorities can be trusted to make good decisions on GMOs."

Labeling

One of the major battlegrounds in terms of public trust is the issue of labeling. In almost every survey upwards of 85% (and sometimes up to 98%) of people want GM foods labeled clearly. Most consumers believe they have the right to know what they are eating and have the right to choose not to eat GM foods if they are uncertain about them. The acceptance rate for GM food rises significantly in most surveys if all GM foods were to be clearly labeled.

Safety

Underlying ideas of trust, labeling, literacy, and use is the consumer's uncertainty about the environmental and consumptive safety of GM food. According to several surveys, if a consumer has heard of a setback or problem with GM food production or consumption (regardless of whether the concerns have validity or not), they are far more likely to reject GM food.

It would seem that the media would thus play a huge role in the reception of GM food. Surprisingly, a study of media coverage showed that the GM foods are portrayed in a more positive light in Europe than in the USA. However, pro- and anti-GM food campaigns continue to be argued primarily through the media.

Media coverage of the Starlink corn issue certainly polarized public opinion in the USA at the time of the recall. In this case the media did little to explain that the product was recalled not because it was unsafe, but rather because it had only received approval for animal, not human food.

Perception of Benefit

For many there is a perception that only agribusiness benefits. Farmers benefit by being able to grow more grain on less space, to improve resistance to weather and disease, and to reduce or eliminate the use of herbicides and pesticides. While these all reduce the farmer's cost and increase profit, consumers fail to realize that they also benefit by having less land devoted to food and grain production. Many consumers fail to consider environmental benefits from less pesticide and herbicide spraying and water quality benefits with decreased pesticide runoff. Until consumers actually believe and see that rice can have more vitamin A, sorghum with more available

minerals and fewer toxic factors, protein, wheat without the protein sequence that causes gluten intolerance, and grains that are less allergenic, there will still be large pockets of consumer resistance.

Golden rice is perceived by many as an example of biotechnology's promise. Every year, over half a million children in developing countries suffer from preventable blindness. Rice has been genetically engineered to contain the carotenoid precursor of vitamin A. This genetically engineered rice is referred to as "golden rice" because of its yellowish color. In 2001 two biotechnology companies, Greenovation and Syngenta offered the GM rice to small-scale farmers in developing countries free of charge and without limitations for humanitarian purposes. Because rice is already a staple crop in developing countries, the vitamin A containing rice would allow people in such areas to obtain more dietary vitamin A and potentially reduce blindness and other effects of vitamin A deficiency.

Interestingly, golden rice set off a major debate. Activist groups such as Greenpeace have tried to discredit the gesture by stating that the rice will not provide enough vitamin A and that it will fail to address blindness because of other malnourishment. The Rockefeller Foundation, a funder of the development of golden rice, says that the calculations of the activist groups about the amount of rice that needs to be eaten to address the vitamin A problems are based on some of the first versions of the rice and are not accurate for more currently available rice with greater vitamin A levels. The issue of golden rice has even split members of Greenpeace into those who oppose the technology under any circumstances and those who believe that this rice has a useful purpose and do not want to oppose the humanitarian effort.

Price

Two contradictory studies show that product price may or may not be important to consumers. A Canadian study asked whether consumers would buy GM food if it were significantly cheaper and tasted the same. A majority of respondents said that they would. In a separate study conducted by the University of Southern Illinois 56% of UK consumers and 37% of US consumers said that they would be willing to pay a premium for non-GM breakfast cereals. Only 22% in each country said that they would not be willing to do so.

Religion/Morality

There has not been much research on religion and GM food acceptance, but it remains a key factor among consumers according to a Pew Initiative on Food and Biotechnology study conducted in 2001. The study, conducted among people of faith in the USA, showed that in the USA people of faith supported biotechnology less than the rest of the public. It showed that the highest approval rating for biotech was among Jews (55%), followed by Catholics (42%), Protestants (37%), and Muslims (32% approved). The number one reason respondents said they disapproved of biotechnology is that man should not be playing God. (These statistics exist despite approval for GM food by many expert ethicists, including the Nuffield Foundation, the Church of England and even the Vatican.) Unlike groups of consumers that may be swayed by more scientific proof to the safety of GM food or a system of food labeling, those with moral objections to GM food may never be swayed to accept GM food.

Economics/Concentration of Power/SES

Socio-economic status (SES) is also a major factor in determining what consumers think of GM food and grains. Regardless of the overall sentiment in a particular country, most surveys show that consumers in higher SES brackets accept GM food with far more regularity than those in lower SES brackets.

Many consumer groups and policy makers are concerned that GM food will create an even greater inequity between developed and developing nations because developing nations will have to purchase expensive GM seeds from Western companies. Furthermore, farmers in the US and elsewhere have expressed concern over using GM seeds even if it will save them money in production because many countries either have strict labeling requirements or outright bans on GM food. Public perception is waiting to see how the economics of GM food bears out. If the industry fails to convince farmers in developed nations that they can sell the product or in developing nations that the industry can service them without disrupting the local economies, they will further impair their image among the public.

GM grains offer potential for improved yield and nutritional advantages. With careful balancing of environmental and ethical issues, vigilance about allergies and other safety issues, clear consumer education and awareness of sharp cultural differences surrounding GM grains, the potential benefits of this technology can be harvested.

GENOME MAPPING

J D Faris, USDA-ARS, Fargo, ND, USA
B Friebe and B S Gill, Kansas State University, Manhattan, KS, USA

Published by Elsevier Ltd.

Introduction

Genome maps are very similar to road maps except that, instead of traversing across land, they traverse across the chromosomes of an organism. Genetic markers serve as "landmarks" along the chromosome and provide researchers information as to how close they may be to a gene or region of interest. There are two types of genome mapping – physical mapping and genetic linkage mapping – in which distances are measured in terms of base pairs and recombination frequency, respectively.

Genetic markers are differences in the DNA sequence of chromosomes derived from two different parents, and these polymorphisms can be visualized in several different ways. Morphological markers are visible markers, which can be identified by simply observing the phenotypes of individuals. Isozymes are protein variants which, after separation by

electrophoresis, can be visualized by a colorimetric activity assay for the relevant enzyme. DNA markers are visualized by chemical staining of the DNA itself or by fluorescence; they can also be labeled with a radioisotope and then visualized by autoradiography. Genetic polymorphisms can also be monitored by direct sequencing of the DNA itself. Currently, markers of choice are DNA-based markers because of their universal applications, information content, and ease of automation, and these will be discussed in detail.

Molecular Basis of DNA Markers

DNA markers reflect differences in the DNA sequences of two parents of a mapping population. These differences, or polymorphisms, can arise through mutations resulting in a single nucleotide difference, errors in DNA replication, or insertions and deletions of larger tracts of DNA. Restriction enzymes are used routinely in molecular biology and genomics. Restriction enzymes recognize specific DNA sequence palindromes, usually 4, 6, or 8 bp in length, and cleave the DNA at that site. In restriction fragment assays, a single nucleotide differing between two genotypes can result in a genetic marker when the base substitution results in the abolishment of a particular restriction site and, thus, a larger fragment in one genotype compared to the other (Figure 1a). This results in a discrete marker representing an individual's genotype that follows the laws of heredity and can be screened in the progeny. In polymerase chain reaction (PCR)-based assays (see below), a single base substitution within a primer annealing site can render the site noncomplementary and prohibit the fragment from being amplified (Figure 1b). Genotypes with or without the particular base substitution can be distinguished by the absence or presence of an amplicon in PCR-based assays. Thus, single base substitutions are specific to particular restriction enzymes or PCR primers. Rearrangements of the DNA between two restriction sites, or two primer annealing sites, can also generate DNA markers (Figures 1c and 1d). Such rearrangements can usually be detected using several different restriction enzymes or PCR primer sets that flank the rearranged region.

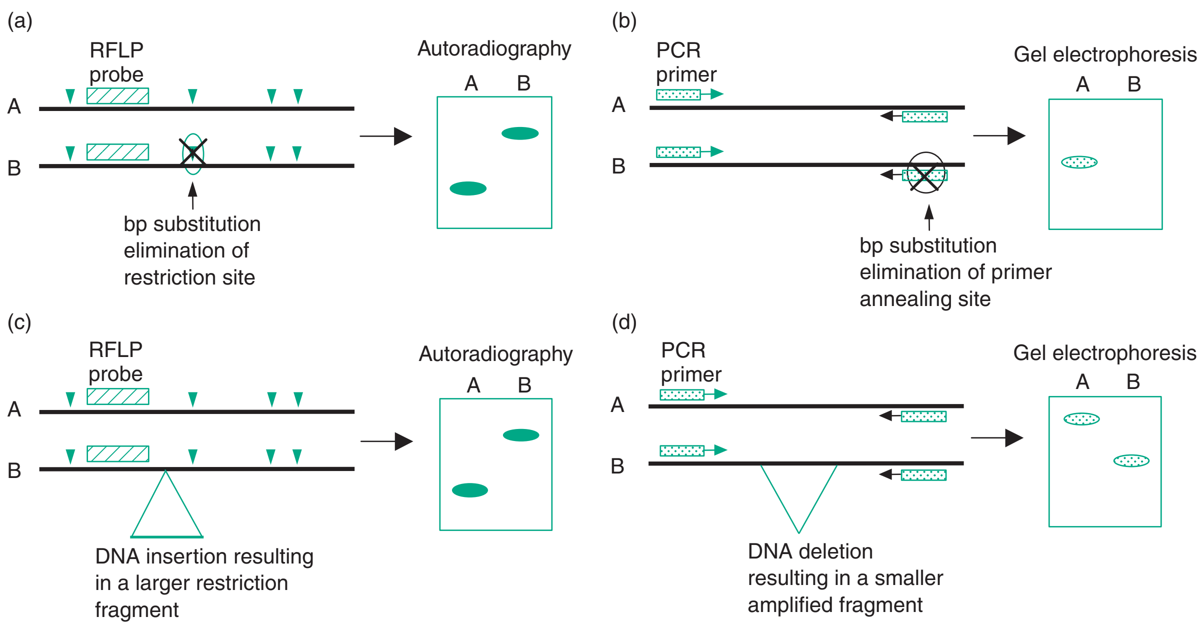

Figure 1 The molecular basis of DNA markers: (a) The DNA of two genotypes (A and B) is digested with a restriction enzyme, which recognizes specific sequences (arrowheads). An RFLP probe, which is a short fragment of DNA, hybridizes to complementary sequences in the A and B genotypes. The fragment detected by the probe in genotype B is larger than that detected in genotype A, because a single base-pair substitution has eliminated one of the flanking restriction sites. The size differences of the hybridizing fragments are visualized as "bands" by autoradiography. (b) PCR analysis of a target sequence in genotypes A and B, where a single base-pair substitution has occurred within the annealing site of the right primer in genotype B resulting in the lack of annealing and, therefore, the absence of an amplicon which is viewed after gel electrophoresis. (c) RFLP analysis of genotypes A and B, where the detected fragment in B has undergone an insertion of a DNA fragment creating a larger restriction fragment than that in A. (d) PCR analysis of genotypes A and B, where genotype B has undergone a deletion of a fragment of DNA between the two priming sites creating a smaller amplicon than that in A.

Methods of Visualizing DNA Markers

DNA markers can be detected in several different ways, some of the most common being restriction fragment length polymorphisms (RFLPs), random amplified polymorphic DNAs (RAPDs), amplified fragment length polymorphisms (AFLPs), sequence tagged sites (STSs, also known as cleaved amplified polymorphic sequences (CAPS)), microsatellites (also known as simple sequence repeats (SSRs)), and single nucleotide polymorphisms (SNPs).

RFLPs are detected by hybridizing a labeled DNA probe, a short piece of DNA usually 0.2–2.0 kbp in length, to genomic DNA that has been digested with a restriction enzyme, separated through an agarose gel, and transferred to a nylon membrane. Hybridized fragments are then observed as "bands" by autoradiography in cases where probes are radioactively labeled (Figure 2a). RFLPs were the first type of DNA markers used that could be applied to essentially any organism, and they are still used routinely in applications such as comparative mapping, map-based cloning, etc. Nonradioactive labeling protocols are now available and used to some extent, which have rendered RFLPs more user friendly. However, due to their relatively low-throughput capabilities, the more user-friendly PCR-based markers are now preferred for generating whole genome maps.

RAPDs, AFLPs, STSs, microsatellites, and SNPs are all PCR-based markers. PCR markers rely on the development of a specific oligonucleotide, or primer, to serve as a start site for amplification. The template

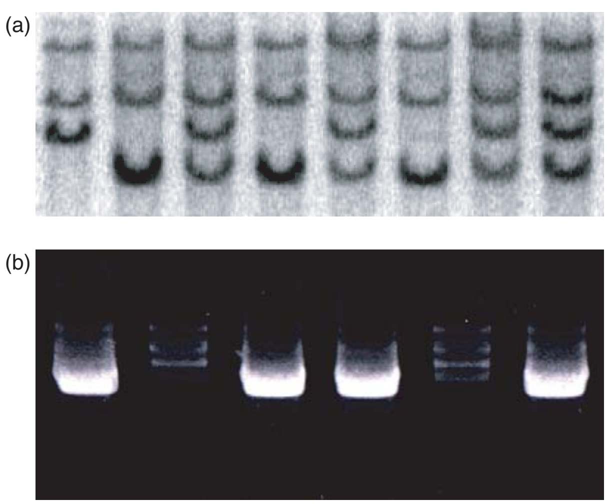

Figure 2 (a) RFLP fragments detected by autoradiography. (b) PCR amplicons detected by agarose gel electrophoresis followed by staining with ethidium bromide and visualization under UV light. The two lanes missing the amplicon are genotypes possessing deletions of the target sequence.

DNA from which a target fragment is to be amplified is mixed together with the primers, nucleotides, and an enzyme that polymerizes DNA (usually *Taq* polymerase). In the PCR process, the samples are first heated to 94–96°C to denature the double stranded target DNA. For the second step, the temperature is lowered to 50–65°C for one to several minutes allowing the left and right primers to anneal to complementary sequences on the target DNA. For the third step, the temperature is raised to 72°C for one to several minutes allowing the *Taq* polymerase to attach at each priming site and extend (synthesize) a new DNA strand. These three steps constitute one cycle. When 30 cycles are performed in succession, the exponential amplification of fragments will result in over one billion copies of the target fragment. Once the PCR is complete, samples are electrophoresed through an agarose or polyacrylamide gel, stained with a chemical, and visualized by UV light or other means (Figure 2b).

RAPD markers are detected using short (10 mer) random oligonucleotides as primers to amplify genomic DNA sequences. RAPDs have not been widely used for genomic mapping because of the unpredictable behavior of the short primers in PCR reactions, which leads to low repeatability.

The AFLP technique combines the use of restriction enzymes with PCR. To detect AFLPs, genomic DNA is digested with two restriction enzymes simultaneously and oligonucleotide adapters are ligated to the ends of the fragments to serve as priming sites. Oligonucleotide primers having from one to three selective nucleotides in addition to the adapter sequence are used in PCR amplification, and the fragments are separated on a polyacrylamide gel. To visualize AFLPs, one primer is end-labeled with radioactivity or fluorescence, or the DNA fragments are directly stained with chemicals. AFLPs provide a very high throughput method for identifying DNA markers as multiple markers can be identified with each restriction enzyme/primer combination. In theory, the number of markers potentially identifiable by AFLP is virtually unlimited, because they are limited only by the number of restriction enzyme/primer combinations surveyed.

Microsatellites consist of di-, tri-, or tetra-nucleotide repeats, and DNA sequences flanking the repeats are used as priming sites in PCR reactions. These short tandemly repeated sequences tend to be imprecisely replicated during DNA synthesis. As a result, the number of repeats within a microsatellite tends to be highly variable even among members of the same species. Therefore, microsatellites tend to produce a high degree of polymorphism. Although microsatellites are costly to identify because of the

amount of sequencing required, once specific primers are constructed they are very user friendly and efficient.

STS markers are usually detected using PCR primers designed on the basis of sequenced RFLP clones that have previously been mapped. Genomic sequences amplified using STS primers are usually digested with a four-base cutter enzyme to reveal polymorphisms. STS markers are also very user friendly and tend to be highly reproducible compared to methods based on arbitrary primers due to the larger primers and increased specificity. Also, STSs can be selected based on prior knowledge of the map position of the corresponding RFLP probe.

SNPs are the most common type of genetic difference between members of the same species. An SNP is a single base-pair difference at a specific site in the DNA. There are many ways of identifying SNPs. Currently, most procedures involve target sequence PCR amplification followed by electrophoresis, sequence detection, or mass spectrometry.

Genetic Linkage Mapping

The high-density genetic linkage maps facilitate map-based cloning experiments, quantitative trait mapping, marker-assisted breeding, and evolutionary studies (for further related readings, *see* **Genomics**). Genetic mapping relies on the fact that nuclear genomes are made up of chromosomes, which contain both genes and noncoding DNA. When homologous chromosomes pair at meiosis, they recombine at various positions along the chromosomes. Thus, recombination is the basis for genetic linkage mapping and determining the order of markers along the chromosome, i.e., markers are separated by genetic distances calculated based on the amount of meiotic recombination that occurs between them.

An example of genetic linkage mapping of three linked markers in 20 F_2 progeny is presented in Figure 3. The markers include two DNA markers (A and B) and one morphological marker (disease resistance gene “R”). The DNA markers are co-dominant and, therefore, all possible genotypes can be determined in the F_2 progeny (homozygous for parent A, homozygous for parent B, and heterozygous). For the morphological marker, disease resistance is dominant and, therefore, the genotypic classes of heterozygous and homozygous for the resistant parent (parent A) cannot be distinguished (resistant plants can have allelic compositions of “RR” or “Rr,” and susceptible plants have “rr”). Inspection

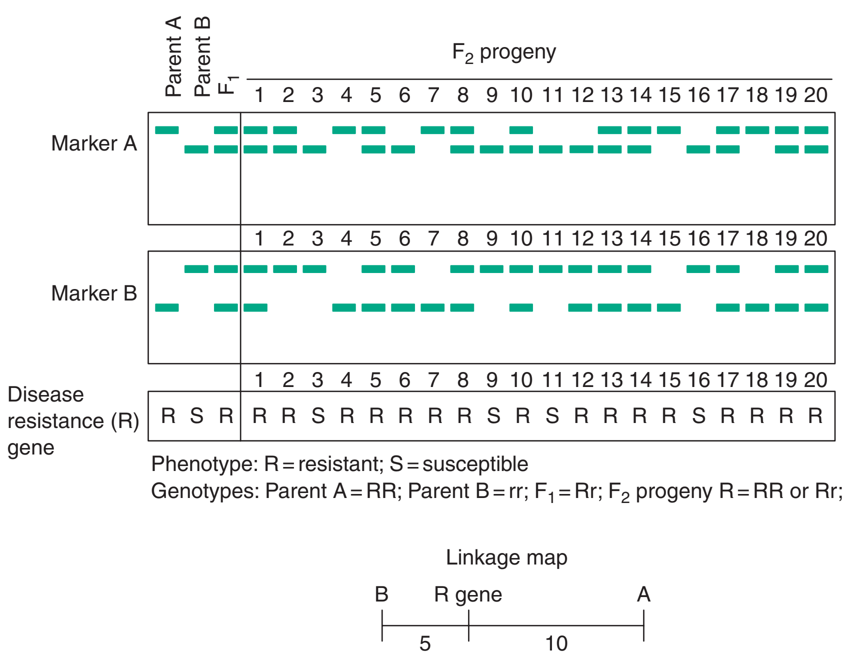

Figure 3 Genotypic data of two DNA markers (A and B) and phenotypic data of one morphological marker (disease resistance gene “R”) for two parents, the F_1 plant derived from crossing the two parents, and 20 F_2 individuals. The DNA markers are co-dominant; thus, all possible genotypes can be distinguished (homozygous for parent A, heterozygous, and homozygous for parent B). The morphological marker “R” is dominant and therefore the genotypes of resistant F_2 individuals cannot be distinguished (resistant plants can be either homozygous for parent A (RR) or heterozygous (rr)). The resulting genetic linkage map of the three loci and genetic distances separating them is shown at the bottom.

of Figure 3 indicates that there are three individuals (2, 6, 12) with genotypes that differ between markers A and B. Between A and R, there are two individuals (6 and 12) with differing genotypes, and one individual (2) has differing genotypes between markers B and R. This suggests that marker R (disease resistance gene) lies between markers A and B. The two recombination events between markers A and R translate into 10 map units ($2/20 \times 100 = 10$), and there are 5 map units between markers B and R ($1/20 \times 100 = 5$).

This type of analysis can be applied to hundreds, or even thousands of markers to construct complete genetic linkage maps of chromosomes. Fortunately, there are various computer software programs available to handle such large datasets and to determine the most likely marker orders and intermarker distances.

The number of individuals surveyed in a mapping population determines the precision of the genetic distance measured. In the example, only 20 individuals were surveyed, and if no recombinants were identified between two markers, this would translate to a genetic distance of 0 map units between the markers. If 100 individuals were surveyed, then one or more recombinants may be identified leading to a genetic distance of 1 or more map units. Generally, initial genetic maps of plant species are generated using 80–120 individuals, which allows for the detection of recombination between markers 1–3 map units apart. This level of precision is considered acceptable and, at the same time, the amount of labor and cost is considered manageable. However, certain mapping experiments such as map-based cloning of genes by chromosome walking require much higher resolution in order to separate markers extremely close to the target gene. In these experiments, it is not uncommon to survey 3000–5000 individuals to obtain the necessary level of precision.

In plants, most populations are derived from crossing two highly homozygous parents. The population shown in the example in Figure 3 is an F_2 population. While F_2 populations are commonly used and generally a good choice for chromosome mapping, other types of populations – such as backcross (BC), doubled haploid (DH), and recombinant inbred (RI) – are also commonly used. However, DH technology is not easily accomplished in some crops, and it is currently impossible in others. Each type of population has its advantages and disadvantages. F_2, BC, and DH populations can be developed very rapidly, while RI populations are developed by advancing each line by single-seed descent for many generations with the goal of selfing to homozygosity. F_2 and BC populations are short lived and provide limited opportunity to obtain DNA and phenotypic data, while DH and RI populations provide essentially pure lines that enable them to be tested for traits in replicated experiments over several environments if desired. Thus, RI and DH populations are preferred for mapping of quantitative traits that may be affected by environmental influences. F_2, BC, and DH populations have undergone only one cycle of meiosis, but an F_2 population has undergone recombination along two homologous chromosomes, and, therefore, provides twice the recombination information as BC or DH. RI populations have undergone several cycles of meiosis but contain two identical homologues and, therefore, provide about the same amount of information as an F_2.

The development and analysis of genetic linkage maps lead to an abundance of information regarding genome structure. From a more applied perspective, they provide knowledge regarding the locations of genes and DNA markers associated with them. In a segregating population, morphological markers can be scored and analyzed in the same manner as DNA markers. The difference in scoring for morphological makers compared to DNA markers lies in the fact that, for morphological markers, the genotype is determined based on visualization of the plant's phenotype, whereas DNA markers are scored at the DNA level. For example, a population segregating for resistance to a particular disease would be scored based on the reaction of each individual to the disease as being one of either parental type. Inclusion of this phenotypic data with genotypic DNA marker data for map generation might reveal that the disease resistance gene is flanked by closely linked DNA markers. Such markers are valuable tools that can be employed by plant breeders, who wish to move the disease resistance gene into elite lines for the development of new and improved varieties. Using the markers to make selections is known as marker-assisted selection (MAS). MAS has advantages over selecting for the trait itself in that markers are not affected by environmental factors as phenotypic traits sometimes are. In addition, MAS allows breeders to make selections in early generations and growth stages, allowing them to eliminate undesirable material early on.

Physical Mapping

In contrast to genetic mapping where distances between landmarks are calculated based on the percent recombination that occurs between them, physical mapping determines actual physical distance. Physical mapping can be done cytologically by chemically staining and viewing whole chromosomes using

techniques such as *in situ* hybridization and C-banding. Such techniques have very low resolution in terms of physical mapping, because chromosomes are viewed at the cellular level usually at metaphase. However, recent techniques such as fiber fluorescence *in situ* hybridization (FISH) where nuclear DNA is lysed on a glass slide and used for *in situ* mapping can provide a much higher resolution (see below). The highest-resolution physical mapping is obtained by sequencing the DNA itself. It is usually preceded by constructing local contiguous sequences (contigs) of large-insert DNA clones and anchoring the contig to a genetic map.

In Situ Hybridization

The *in situ* hybridization (ISH) technique was developed in the 1970s and allows the localization of genes or DNA sequences directly on chromosomes in cytological preparations. The ISH technique uses probe DNA that is labeled with biotinylated dUTP or digoxygenin-dUTP, and the hybridization sites are detected by enzymatic reporter molecules such as horseradish peroxidase or alkaline phosphatase conjugated avidin/streptavidin. ISH has been used successfully to determine the physical location and distribution of dispersed or tandemly repetitive DNA sequences on individual chromosomes. For example, it has been used to determine the physical location of multicopy gene families such as the 5S and 18S–26S ribosomal genes.

FISH uses fluorochromes for signal detection. The FISH technique allows different DNA probes to be labeled with different fluorochromes that emit different colors (multicolor FISH). Thus, the physical order of two or more probes on a chromosome can be determined simultaneously. Also, FISH can allow more precise mapping of probes, because the fluorescent signals can be analyzed with special cameras and digital imaging tools.

In humans, the order of two DNA probes can be determined by ISH on metaphase chromosomes only if the two sequences are separated by at least 1 Mb. However, when ISH is done using interphase nuclei, DNA sequences separated by as little as 50 kb can be resolved. Plant metaphase chromosomes are more condensed than human metaphase chromosomes, and this may be one reason why ISH using low-copy probes is more difficult in some plant species. Thus, it has been suggested that interphase nuclei be exploited for ISH mapping in plants. Subsequently, experiments where DNA probes were hybridized to maize interphase nuclei suggested that the resolving power of interphase FISH mapping can be as little as 100 kb.

More recently, the FISH technique has been used successfully to determine the physical location of bacterial artificial chromosome (BAC) clones on interphase and metaphase chromosomes. Rice BAC clones have been hybridized to rice (*Oryza sativa* L.) chromosomes revealing that the repetitive DNA sequences in the BAC clones could be efficiently suppressed by using rice genomic DNA as a competitor in the hybridization mixture. The successful application of this technique to plants with very large genomes may depend on the size of the genomic clones analyzed and the amount of repetitive sequences in the genome.

Fiber FISH

Many plant species have small chromosomes that are not suitable for classical genetic studies and ISH analysis of metaphase chromosomes. A new FISH technique that uses extended DNA fibers has been developed. In the fiber FISH technique, chromatin fibers are extended across a glass slide and a probe is labeled as with standard FISH and hybridized to the extended fibers. In humans, fiber FISH has been used to analyze overlapping clones, detect chromosomal rearrangements, determine the physical distances between genes, measure the sizes of long DNA loci, and aid in the positional cloning of specific genes. Fiber FISH was used in *Arabidopsis thaliana* to measure clusters of DNA repeats as long as 1.71 Mb, which is more than 1% of the *Arabidopsis* genome. However, it was found that fiber FISH signals derived from small DNA fragments (<3 kb) were often observed as single spots on extended DNA fibers, and it was concluded that these signals were difficult to distinguish from background noise.

Aneuploid Mapping

Wheat is unique in that it can tolerate a high degree of aneuploidy (abnormal chromosome number, compliment, or constitution) because of its polyploid buffering capacity. Some of the most important and useful genetics stocks ever developed in wheat are the nullisomic–tetrasomic (NT) lines and the ditelosomic (dt) lines. NT lines are lacking one pair of chromosomes and the absence of the pair is compensated for by an extra pair of homoeologous chromosomes. Ditelosomic lines are lacking one pair of chromosome arms. For example, the line dt1AS has the complete normal chromosome constitution except that the long arms of the pair of 1A chromosomes are missing. For more information on the aneuploids of wheat, *see* **Wheat**: Genetics.

With today's molecular technology, the power and utility of the wheat aneuploids is even more greatly

realized. DNA markers can be quickly located to a specific chromosome or chromosome arm using a single hybridization or amplification reaction without the need for polymorphism. Chromosomal arm maps have been developed that locate DNA clones to specific chromosome arms. These maps are useful in that they can be applied to gene tagging, linkage and mapping of QTLs, cytogenetic manipulations, estimation of genetic distance, and evolutionary studies.

Due to their polyploid buffering capacity, wheat and other polyploids are more amenable to cytogenetic manipulations than diploid plant species. However, cytogenetic stocks such as primary trisomics have been developed in plant crops such as tomato, rice, and soybean (*see* **Rice**: Genetics and **Soybean**: Germplasm, Breeding, and Genetics). A primary trisomic individual contains a normal chromosome complement plus an extra complete chromosome ($2n = 2x + 1$), and it can be used as a tool to locate genes and specific genetic linkage groups (maps) to specific chromosomes. Trisomics cause segregation distortion in critical F_2 populations for phenotypic traits and DNA-based markers. For example, a DNA marker is selected from a previously developed genetic linkage map and used to screen a complete set of primary trisomic populations. The marker will segregate in a Mendelian fashion in all populations except for the critical one, i.e., the population derived from the trisomic that harbors the DNA sequence detected by the DNA marker. Using this method, genetic linkage groups can be assigned to their corresponding chromosomes.

Chromosome Deletion Mapping

Another unique system in wheat is the use of gametocidal (*Gc*) factors to construct chromosome deletion lines. *Gc* chromosomes are introduced into wheat by interspecific hybridization with the related *Aegilops* species and backcrossing. Plants monosomic for the *Gc* chromosome produce two types of gametes. Only those gametes possessing the *Gc* chromosome are normal. Gametes lacking the *Gc* chromosome undergo structural chromosome aberrations and, in most cases, are nonfunctional. However, if the damage caused by the chromosome breakage is not sufficient to kill the gamete, it may still function and be transmitted to the offspring.

The *Gc* system has been used to develop wheat lines with terminal chromosome deletions. These stocks have proven very useful for the physical mapping of genes and DNA markers to subarm locations and for the development of physical maps, which have been constructed for all seven homoeologous chromosome groups of wheat. In addition, chromosome bin maps of most of the expressed genes in the wheat plant have been constructed using a set of wheat aneuploid and deletion lines (http://wheat.pw.usda.gov/wEST/binmaps/).

Terminal chromosome deletions have also been used to construct physical maps in maize. The *r-XI* system, a small intercalary submicroscopic deletion located on the long arm of chromosome 10 in maize, has been shown to induce terminal deletions and monosomy. Terminal chromosome deficiencies have been developed using *r-XI* and identified with recessive morphological markers. RFLP markers were physically mapped in relation to terminal deletions occurring on various chromosome arms. Some insights were gained regarding physical distances between markers, but discrepancies in marker order along the physical maps compared to the genetic maps were observed suggesting that multiple rearrangements may have occurred in the deletion lines. A major disadvantage to this system is that utilization of the terminal deletion lines in maize for long-term physical mapping is impossible. The lines cannot be propagated because maize is diploid and many of the genes are unique in the maize genome. For more information on maize, *see* **Maize**: Genetics.

Large-Insert Clone Contigs

The construction of physical contig maps is important for facilitating positional cloning of genes, sequencing of genomic DNA, and detailed analysis of chromosome and genome structure. Physical contig mapping is the arrangement of large-insert clones (yeast artificial chromosomes (YACs), BACs, cosmids) in a linear array that represents the DNA sequence along the chromosome.

Clones are selected by screening a library with DNA probes used to detect genetic markers on a genetic linkage map of the organism. Several DNA probes that detect closely linked genetic loci will hybridize to corresponding large-insert clones, and these clones can then be arranged into a contig based on overlapping segments and fingerprinting. YAC and BAC contigs are currently being developed in many crop species.

Once a physical contig map is complete, the structure and organization of the genome, such as the distribution of repetitive and single-copy sequences, can be discerned. Large-insert clone libraries have been developed for many plant species, but in most cases it is not yet a priority to develop contigs that cover entire genomes. Instead, the large-insert libraries are being used to construct small localized contigs of genomic regions that possess genes of interest.

Comparing Physical Distance to Genetic Distance

Physical maps have led to a wealth of information regarding the physical locations of morphological traits and evolutionary translocation breakpoints, and genome-wide structure and organization. Comparisons of the physical maps with genetic linkage maps can reveal the physical distribution of genes and recombination along the chromosome. For example, RFLP probes derived from mRNA (called cDNA probes) represent expressed genes and, thus, the physical mapping of cDNA probes will reveal the physical locations of expressed genes. Therefore, when sets of cDNA probes are mapped genetically as well as physically, one can infer the relationship between physical distances and genetic distances among the common markers. In wheat, physical maps constructed using the chromosome deletion lines have been compared extensively to corresponding genetic maps of the same chromosomes. This work has revealed that genes and DNA markers tend to be clustered in small physical segments that undergo a high degree of recombination (**Figure 4**). The gene-rich regions are separated by large gene-poor segments that undergo very little recombination. This work has facilitated BAC contig construction of regions containing genes of interest for the purpose of positional cloning.

In barley, physical maps generated based on translocation breakpoints were compared to corresponding genetic linkage maps. The results agreed with those found in wheat by deletion mapping and showed that the barley genome consists of relatively small gene-rich regions that are hot spots for recombination interspersed among large segments that are gene poor and undergo very little recombination. The information obtained by physical mapping of translocation breakpoints has facilitated the construction of BAC contigs and positional cloning of important genes by allowing researchers to focus on the gene-rich regions of the genome (for further reading, *see* **Barley**: Genetics and Breeding and **Genomics**).

More intricate comparisons of physical and genetic relationships can be obtained by comparing local BAC contigs to genetic maps. The primary goal of such experiments is to identify a large-insert clone containing the gene of interest, but additional important information is obtained. For example, once a physical contig map of the region is developed, it can be compared to the genetic linkage map of the corresponding region to calculate physical to genetic distance ratios. This is important information because recombination is known to be distributed nonrandomly throughout the genomes of many plant species causing the physical to genetic distance ratios to be highly variable depending on the characteristics of the region. Such information allows the investigator to determine the physical distance between the gene of interest and the closest DNA markers on the genetic map.

Comparative Mapping

Much effort has been put forth in comparing the genomic relationships among grasses and among members of other plant families. For example, comparative mapping experiments among members of the Poaceae such as wheat, rice, barley, rye, oat, and maize have revealed remarkable similarities in gene content and marker synteny at the chromosome level. It is well established that DNA probes cloned from these related species commonly identify sets of orthologous loci that lie at approximately the same positions relative to each other and to the centromeres. Consensus maps of several chromosomes uniting loci from homoeologous wheat genomes and the corresponding chromosomes of barley, *Ae. tauschii, T. monococcum*, and rice have been presented. These experiments have shown that the genomes of barley, *Ae. tauschii*, and *T. monococcum* are essentially collinear with wheat genomes. The genomes of more distantly related cereals such as oat, rice, and maize can be divided into linkage blocks that have homology to corresponding segments of the wheat genome.

The degree of genomic similarities observed at the chromosome level among grass genomes led to the notion that information from the small genome of rice could be directly applied to the much larger genome of wheat. However, even though a substantial degree of synteny is observed at the chromosome level, studies of the degree of microcollinearity between rice and wheat show less promise for gene discovery in wheat.

Future Mapping Prospects

The ultimate goal in map construction is the deciphering of the linear DNA sequences of the full complement of chromosomes of an organism. Breakthroughs in high-throughput DNA sequencing have led to the complete sequencing of the five pairs of chromosomes of *Arabidopsis* (genome size 126 Mb, see http://mips.gsf.de/proj/thal/) and the target is within reach for the 12 pairs of rice chromosomes (genome size 426 Mb, see http://www.usricegenome.org/) (*see* **Rice**: Genetics). In large genome crops such as barley ($\sim 5.3 \times 10^6$ bp) and wheat ($\sim 16 \times 10^6$ bp), more than 80% of DNA consists of repetitive elements making it difficult to sequence

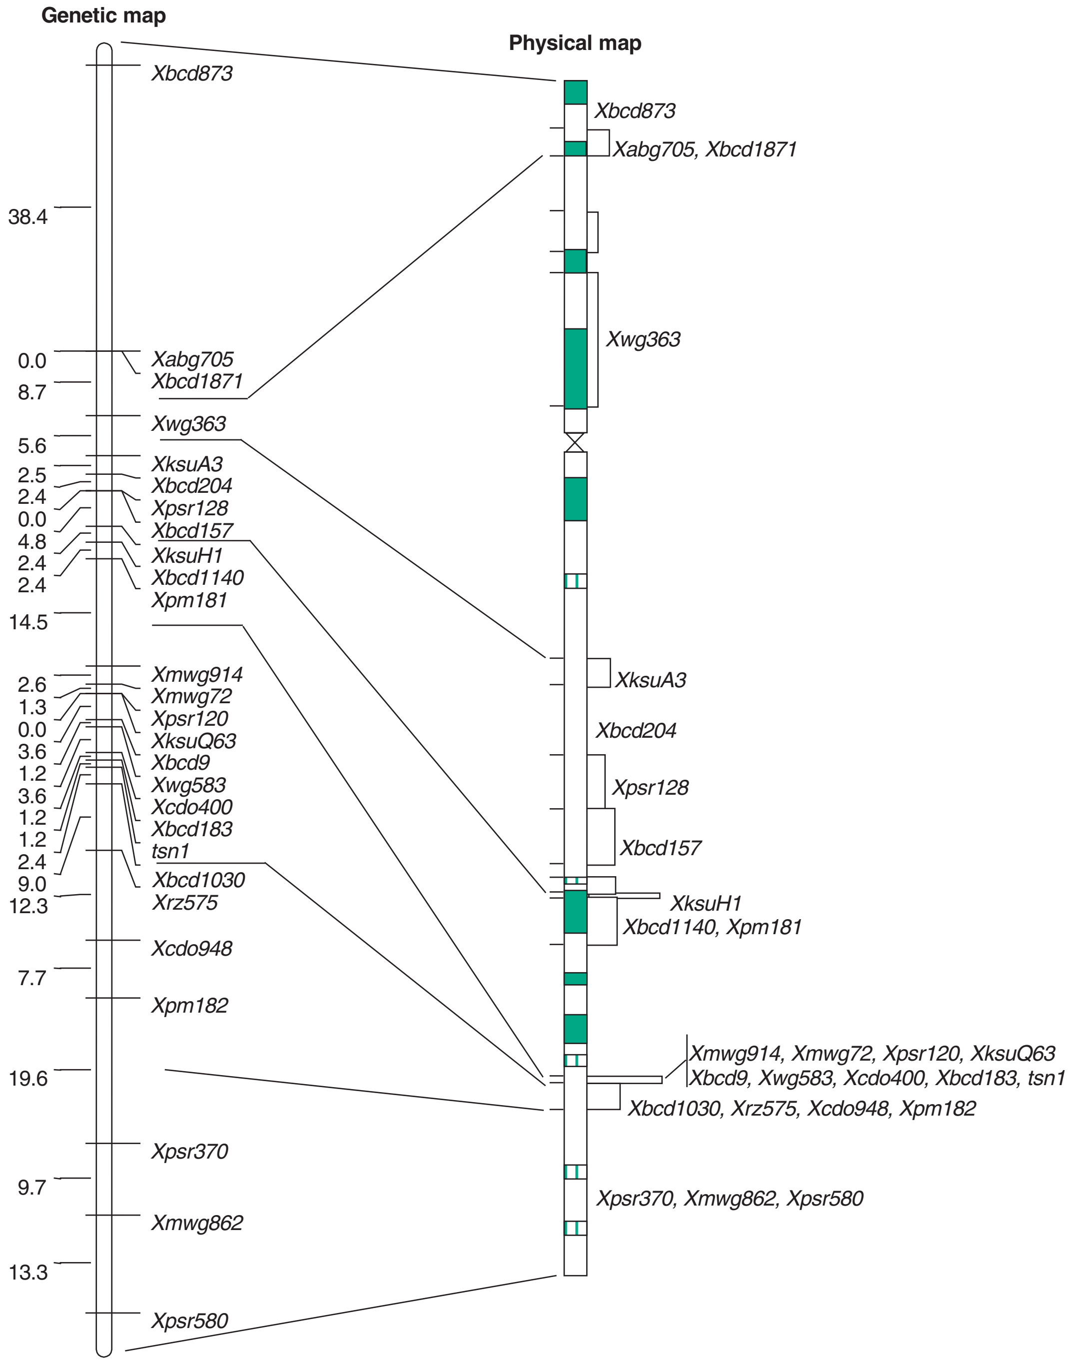

Figure 4 Wheat chromosome 5B genetic linkage map (left) compared to the physical map (right). The genetic linkage map was constructed using a BC population and the physical map was constructed using the chromosome deletion lines of wheat. On the genetic linkage map, units separating markers are shown on the left, and markers are indicated on the right. On the physical map, tick marks on the left of the chromosome indicate deletion breakpoints, black and hatched regions on the chromosome represent dark and light C-bands, respectively, and DNA markers and their bin locations are shown to the right. Lines drawn between the maps indicate where deletion breakpoints occur relative to the genetic map. Notice that the centromeric region is nearly void of DNA markers and recombination, while more distal regions possess most of the DNA markers and recombination.

the entire genome. However, gene-rich regions can be targeted for sequencing as is already being done for maize (http://www.zmdb.iastate.edu/), and plans are underway for such a project in wheat. The goal will be to determine the genomic as well as full-length cDNA sequences of the entire set of genes in all organisms of economic significance. Once genomic and DNA sequence of most genes is known, the techniques

such as SNPs will become very important for analyzing allelic variation of useful genes (gene mining) in diverse germplasm for novel gene discovery and manipulation for crop improvement.

GENOMICS

G B Fincher and P Langridge, University of Adelaide, Glen Osmond, SA, Australia

Introduction

Emerging techniques of functional genomics are being enthusiastically embraced in both the private and public sectors of scientific endeavor. Although the techniques have been developed relatively recently, they have quickly evolved and expanded into an exciting set of technologies that is attracting massive research investment around the world. It remains difficult to come up with a succinct, yet informative definition of functional genomics and its related technologies, but the ultimate objectives of the technologies are clear. The following would together constitute an ideal end point for genomics studies:

- the determination of the complete nucleotide sequence of a genome,
- the identification of all the structural genes in that sequence,
- well-defined functions for all the genes,
- a detailed knowledge of the regulatory control of the genes during normal growth and development, and in response to environmental stresses, and
- an understanding of the complex interactions that occur in genetic and cellular networks.

Thus, in functional genomics one is endeavoring to determine the function of large sets of genes or, ideally, the entire genetic complement of an organism. Functional genomics then draws the profiling of proteins and metabolites into the analysis. If the ambitious goals outlined above are to be achieved

in a reasonable time frame, given that plants might have between 25 000 and 40 000 genes, the attendant technologies must allow high throughput collection of data and high throughput analyses of gene structure and function. It is also becoming clear that the noncoding regions of the genome play a critical role in various aspects of genome behavior and gene expression. Analysis of these regions poses special problems that have not yet been addressed in plant genomics.

The key feature of genomics and associated technologies is that they represent a fundamental change in our approach to biological science. In the past, we usually investigated a biological phenomenon with a particular hypothesis in mind, and with one or a small number of genes or gene products in our sights. For example, a starting hypothesis that a plant's response to salt stress might be linked with the capacity of Na^+ transporters to move Na^+ ions across various cellular membranes would have focused experiments on measuring changes in these transporters at the gene expression or biochemical levels. In contrast, the genomics approach involves no preconceived ideas as to what genes or proteins might be involved, in a particular phenomenon, but instead involves the high throughput collection and analysis of data in a broader, nonbiased manner. In the salt stress example, this would entail application of the stress to the plant and the subsequent collection of expression data for as many genes as possible. Identification of all up- and down-regulated genes would follow, together with attempts to rationalize the shifts in gene expression with the plant's response to salt stress on a much broader scale. This broad approach can easily be justified, not only because genes seldom act alone, but also because it acknowledges the high level of complexity of cellular networks and the participation of multiple genes or proteins in plant processes. Although genomics technologies adopt this broad approach, this is not to say that the technologies cannot be focused on more specific components of an overall phenomenon. In the salt stress example it might be desirable to limit the study to effects on ion carriers or pumps. Conversely, genomics methods can generate an overwhelming amount of data that present major difficulties for subsequent analysis of the process. Salt stress is an example of the latter, because up to 25% of genes in plant systems can be up- or down-regulated in response to the stress.

Genomics technologies were initially developed on model organisms such as the yeast *Saccharomyces cerevisiae*, the nematode *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, mice, and humans. An early decision to use *Arabidopsis thaliana* as the model for genomics studies in plants was based largely on the relatively small genome of this plant and its short life cycle. Attention soon turned to the commercially important cereals – rice, wheat, maize, and barley. These species are members of the Poaceae family, and together provide the vast majority of carbohydrate requirements in human diets. At the same time, the technology was becoming broader in its scope. Early transcript analyses showed that mRNA levels are not necessarily related to cellular levels of the protein products of the mRNA; this led to an interest in defining the complement of proteins in plant tissues grown under various conditions, and became known as proteomics. Moreover, protein levels themselves were often difficult to relate to a cellular response; this led, in turn, to an interest in metabolite profiles in plants as the ultimate reflection of gene expression in cellular processes. Metabolomics had evolved.

In this article, we will outline the essential features of the genomics, proteomics, and metabolomics technologies as they apply to the common cereals, and how they are used in a complementary manner to generate a list of candidate genes that jointly control the phenomenon of interest. Once the candidate genes are identified, their participation in a particular cellular function must be confirmed. The major strategies for functional analysis currently in use for this purpose will be summarized. As mentioned above, coupling genomics, proteomics, and metabolomics technologies with functional analyses of genes is referred to here simply as functional genomics. The high throughput imperatives of functional genomics programs require the development of specialized equipment, such as robots, automated mass spectrometers, and high capacity nucleotide sequencers. It should also be emphasized that functional genomics would not be possible without the spectacular evolution of computing power that has occurred since the early 1990s. These points will be illustrated by reference to our functional genomics programs on early grain development and cell wall biosynthesis in wheat and barley. Other specialized resources, including mutant libraries and high-density genetic maps, represent critical support technology for functional genomics programs. Finally, the potential economic, social, and environmental benefits that might flow to cereal producers and consumers as a result of functional genomics programs will be explored.

Genome Analysis

The traditional use by cereal breeders of phenotypic markers in selection of superior quality and productivity traits was significantly enhanced through the

development of DNA molecular markers in the 1980s. In particular, restriction fragment length polymorphisms (RFLPs) allowed the first molecular analysis of cereal genomes. Subsequently, amplified fragment length polymorphisms (AFLPs), randomly amplified polymorphic DNAs (RAPDs), simple sequence repeats (SSRs or microsatellites), and single nucleotide polymorphisms (SNPs) have been developed as additional methods for the generation of high-density genetic maps of cereals. Furthermore, quantitative trait loci (QTLs) controlling complex, polygenic traits, can be mapped, so that major genetic loci that influence traits such as components of quality, tolerance to stresses such as drought, kernel weight, seed dormancy, and susceptibility to mineral toxicity in soils can be incorporated into the genetic maps. Similarly, cloned genes can be readily mapped, provided polymorphisms can be detected in or around the genes of parental lines used to generate the mapping populations. High-density genetic maps are now available for wheat, barley, maize, sorghum, and rice. The extremely large size of the wheat hexaploid genome and its inherently low level of polymorphism initially hampered the development of genetic maps for this cereal, although better progress is now being made with AFLP and microsatellite markers.

Distances between markers or genes on genetic maps of the type described above are based on recombination frequency in segregating populations, and this frequency will vary in different regions of the genome. In contrast, physical distances represent the actual DNA sequence distances between markers or genes, expressed precisely in terms of the number of nucleotide pairs in the DNA. Increasing attention is being focused on the generation of physical maps, at least in gene-rich regions of the genome. The availability of bacterial artificial chromosome (BAC) libraries for the common cereals (Table 1), in which large fragments of genomic DNA are cloned, has greatly assisted in the generation of the physical maps of selected regions of cereal genomes. Physical maps of the genome can be constructed by fingerprinting large collections of BAC clones and using the fingerprints to link BAC clones. Such physical maps have been constructed for the rice and maize genomes, and are well advanced for *Aegilops tauschii*, the D-genome progenitor of bread wheat. At a smaller scale, BAC clones can be used to rapidly sequence and characterize the regions surrounding particular genes. If, for example, a cellulose synthase (*CesA*) gene or genes were detected on a particular BAC clone, high throughput sequencing and restriction mapping protocols could be used to develop a physical map of the relevant regions of the BAC clone or series of overlapping BAC clones.

Table 1 Genomic resources for the major cereals

Cereal species	*Genome size (bp)*	*BAC libraries*	*Public ESTS (June 2003)*	*Genetic maps*	*Genome sequence*
Rice	4.3×10^8 (diploid)	Yes	202 000	Yes	Available in draft form (2002)
Wheat	1.6×10^{10} (hexaploid)	Yes	420 000	Yes	No
Barley	5×10^9 (diploid)	Yes	346 000	Yes	No
Maize	2.5×10^9 (diploid)	Yes	229 000	Yes	Perhaps by 2006?

The logical extension to the sequencing and physical mapping of local regions of cereal genomes is to sequence the entire genome. Rice has a genome size of $\sim 4.3 \times 10^8$ bp, which is considerably smaller than the genome sizes of the other major cereals (Table 1). In addition, an abundance of rice BAC libraries and other genetic resources meant that rice was seen as the cereal genome of choice for complete sequencing. Draft versions of the rice genome sequence have recently been released into the public databases. The genomes of other cereals are at least tenfold larger than those of rice (Table 1) and it will be some time before their complete sequences are determined. Nevertheless, targeted genome sequencing is another route to obtaining valuable physical map information for the larger cereal genomes. Irrespective of their overall size, most cereal genomes contain about the same number of genes. The number of genes has been variously estimated in the range 25 000–40 000. In cereals, the species differences in genome size lie not so much in differences in gene number, but rather in differences in the amount of tandem and dispersed repetitive DNA elements that constitute a large proportion of these genomes. It is becoming clear that active genes are concentrated in "gene-rich" regions, and there are several procedures that enable these gene-rich islands to be located and sequenced. Thus, a major effort can be directed towards sequencing and physical mapping of the gene-rich regions of the larger cereal genomes. However, the plant genome sequencing programs indicate that the analysis of the noncoding regions will also provide many important clues about genome structure and function.

Finally, the observation that cereal genomes are syntenous has greatly assisted the cross-referencing of genome sequences and genetic maps between different cereal species. Synteny is the phenomenon in which the order of individual genes along a segment

of the genomes of different cereals is conserved, despite large variations in genome size. Thus, if the order of genes can be determined along a region of the rice genome during sequencing, it is highly likely that the same genes will be arranged in the same order along the homologous region of the wheat or barley genomes. The syntenous regions might be discontinuous, through translocation events that rearrange chromosome segments, but once the homologous region is identified the order of genes therein is usually conserved. Synteny is attributable to the common ancestry of extant cereal species and, although not always perfect and not applicable to all regions of the genome, it does add enormous value to the rice genome-sequencing project, because relative gene and molecular marker positions can be extrapolated across species. Thus, synteny across the cereals and the availability of the rice genome sequence has become a critically important tool in cereal genomics (Figure 1). For the important cultivated cereals such as wheat, barley, and maize, there is extensive information on the genetic location of major loci affecting a wide range of traits, including quality, disease resistance, abiotic stress tolerance, and various physiological and developmental features. Through the rice genome sequence, the genetic data in these cereals can be linked to the physical location on the rice genome and used to identify candidate regions in the target cereal (Figure 1).

Transcript Analysis

A common strategy for identifying unknown genes that might be related to a particular biological problem is to correlate expression patterns of genes. This is usually done based on the relative abundance of mRNA species and, through existing knowledge on the tissue and time frame in which the process of interest is occurring, to identify candidate genes (Figure 2). For example, it is known that large amounts of a particular polysaccharide, heteroxylan, are deposited in the cell wall at a defined time in elongating barley coleoptiles. Therefore, candidate genes might be identified from abundant mRNAs that appear in the coleoptiles just preceding the increased rate of heteroxylan deposition. The sequence of a cDNA corresponding to the mRNA might be recognized as encoding a protein or enzyme connected with wall synthesis. In this case, cDNAs derived from the *CesA* and cellulose synthase-like (*Csl*) gene families would be of particular interest, given the similarity between xylan and cellulose structure. Northern hybridization analyses are often used to monitor such expression patterns, but they can be relatively insensitive and require probes that presuppose the presence of a particular transcript; unknown genes or genes not previously suspected of having a role in wall synthesis will not be found. It can therefore be argued that it is essential not only to define the time, tissue location, and level of expression

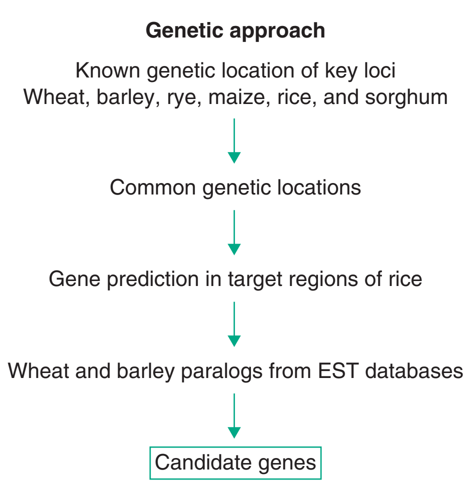

Figure 1 Genetic approach and the use of synteny to identify candidate genes in cereals. The genetic loci that are linked to a specific trait can be cross-referenced to the syntenous region of the rice genetic map. This region of the rice map can be located in the rice genome sequence, and active rice genes in this region can be identified. The corresponding genes from the other cereals are thereby identified as potential candidate genes that might control the trait of interest.

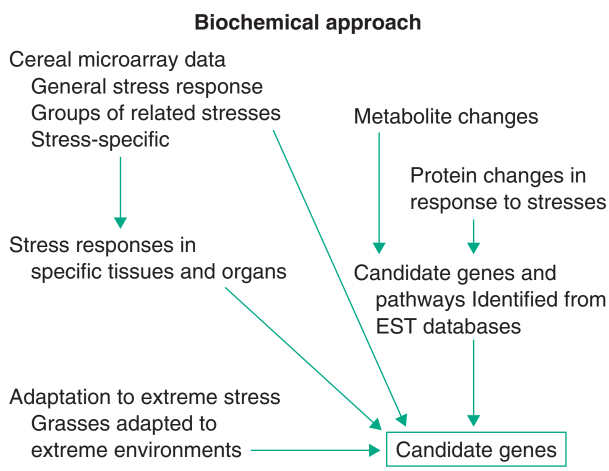

Figure 2 The biochemical approach to the identification of candidate genes. In this example a stress is imposed on the cereal plant, and the responses are monitored at the transcriptional level through microarray data, at the protein and metabolite levels in cell extracts, and through known information on genes that are expressed in well-characterized species that are adapted to the stress of interest. The multi-pronged approach enables the number of genes to be focused to a manageable number for functional analysis.

of a particular gene, but that it is also critical to define other genes that are coordinately expressed during the process under examination. This can be achieved through monitoring the entire transcriptome, i.e., all the transcribed mRNAs that are present in the tissue of interest.

Many early plant genomics projects were therefore focused on the high throughput definition of gene expression, as measured by profiling mRNA transcripts, with the straightforward objective of identifying all genes that were transcribed in a particular tissue at a particular time. This branch of the overall functional genomics technology is now referred to as transcriptomics. Transcript profiling can take several forms. First, mass sequencing of short segments of clones in cDNA libraries can be used to identify genes that are being transcribed. These sequences are known as "expressed sequence tags" (ESTs), and the number of cereal EST sequences in the public databases has increased in spectacular fashion over the last few years, to the point where there are now well over a million ESTs available for the major cereal species (Tables 1 and 2). It must also be remembered that EST sequence data make a major contribution to genome sequencing and physical mapping programs.

In the xylan synthase example, the databases would be searched for all *CesA* and *Csl* gene transcripts, and the ESTs could subsequently be used to isolate and characterize full-length cDNAs for all the genes being transcribed in the tissue of interest. As EST databases increase in size, searches can become semi-quantitative, such that the relative abundance of ESTs in a particular library can be correlated with the abundance of corresponding mRNAs in the tissues from which the libraries were prepared. Nevertheless, there are a number of inherent problems associated with EST analyses, including the unreliable quality of some sequences in the databases, difficulties in detecting cDNAs from genes that are transcribed at low levels, the incomplete nature of the sequences, and the fact that the sequences might correspond to nonconserved $5'$ or $3'$ untranslated regions and therefore be difficult to identify. These problems can be especially frustrating when the EST of interest is a member of a multigene family, as is frequently the case in cereals. Computer programs, through which ESTs that represent fragments of the same gene can be clustered and assembled into a single sequence (referred to as a contig), have overcome some of these difficulties.

Alternative but often less precise transcript profiling methods have now been developed. Microarraying technology is one such method that has been steadily improving over recent years. In this technique, large numbers of different gene fragments are immobilized in an ordered array on a solid support, which is variously known as a macroarray, a microarray or a chip, depending on the density of immobilized DNAs. The two main types of array currently in use are the DNA fragment array, where DNA clones, usually cDNAs or oligonucleotides of 40–80 bases, are synthesized and arrayed with a robot at densities of up to 5000 per square centimeter. The second type of array uses shorter oligonucleotides, of 10–12 residues, that are synthesized *in situ* on the surface of the chip at very high densities. The latter array is designed so that a single known gene is represented by several of the short oligonucleotides.

By the end of 2003 it is anticipated that chips comprising over 20 000 genes each will be commercially available for the interrogation of wheat, rice, and barley transcriptomes. To do this, the array is exposed to labeled pools of RNA (or cDNA derived from the RNA pool), from which individuals will

hybridize with the homologous DNA sequences on the array. In this way, an entire population of mRNAs from a tissue can be simultaneously hybridized, in a single experiment, with tens of thousands of known DNA probes that are immobilized at precisely known positions on the array. After the hybridization, the expression levels of each gene can be determined with a high-resolution laser scanner, and computer programs can group genes that are up- or down-regulated in increasingly sophisticated ways.

Although microarray technology is now widely used for transcript profiling, there have been technical and interpretative difficulties associated with accurate arraying of the DNA on the solid support and precise reading of the arrays. In particular, microarrays are not highly accurate and provide only approximations of mRNA levels. Several other, newer transcript profiling techniques have also been developed to help address these limitations, including serial analysis of gene expression (SAGE), restriction fragment differential display (RFDD), and massively parallel signature sequencing (MPSS). As with other genomics technologies, there is a danger that microarray analyses can overwhelm us with data. For example, in looking at changes in mRNA transcipt profiles during the early development of starchy endosperm of cereal grain, large numbers of transcripts are detected and many will follow similar developmental patterns. Faced with hundreds or even thousands of candidate genes of interest, what is the next step in terms of identifying key genes in the process? This could necessitate a refocusing of the experiment, for example, on genes already known to be involved in processes such as cell wall synthesis, and the attendant re-instatement, in part at least, of the hypothesis-driven approach!

In more general terms, profiling of mRNA transcripts is undertaken in the knowledge that mRNA levels and levels of the encoded proteins are not always correlated, for a number of reasons associated with transport, processing, and turnover of macromolecules in the cellular context. This has led to the development of proteomics as another subset of methods within overall functional genomics technologies. Results from proteome analyses can also be used to help narrow down the number of candidate genes identified in microarray experiments (Figure 2).

Proteome Analysis

The proteome may be defined as the complete complement of proteins that is present in a particular tissue under particular conditions. Again there are a number of approaches and components of proteomics technology, which are outlined in more detail in **Proteomics**. Traditionally, protein extracts from tissues of interest have been separated by two-dimensional (2D) gel electrophoresis that involves sequential separations based on size and isoelectric points. Between 1000 and 2000 proteins can be routinely separated on 2D gels, although as many as 10 000 have been resolved using this system. Many of the proteins will represent different isoforms from a single group of proteins, or multiple forms of a single protein with varying levels of post-translational modification. The identification of individual protein spots on the 2D gel can be based upon a combination of amino acid composition, peptide mass spectrometry fingerprinting, NH_2-terminal sequence, molecular mass, and pI data, which are subsequently analyzed through appropriate protein databases (e.g., SWISS-PROT and OWL) and nucleotide databases. These procedures place heavy demands on highly sophisticated equipment, in particular expensive mass spectrometers and powerful computers. A suite of five mass spectrometers in a well-equipped proteomics laboratory might generate 5–10 GB of data everyday. In the example of searching for proteins that might be involved in cell wall biosynthesis, it is advantageous in terms of data management and interpretation to enrich proteins of interest in the tissue extracts prior to 2D gel electrophoresis. Thus, the starting point for the isolation of proteins might be membrane preparations enriched in Golgi, where noncellulosic wall polysaccharide synthases would be expected to be located, or in plasma membranes, where cellulose synthases might be located. The example of cell wall polysaccharide synthases also points to some of the technical problems associated with proteomics. The enzymes are of high molecular mass and are normally membrane-bound. These types of proteins are typically under-represented in 2D gel profiles, and their reliable detection requires more recently developed liquid chromatography procedures (*see* **Proteomics** for more details).

Another key activity in proteomics programs is the investigation of protein–protein interactions that are increasingly recognized as central to cellular function. In our work on the early developing wheat grain, the yeast two-hybrid system is used to progressively build up a picture of multiple interacting proteins that form transcription factor complexes and control the expression of genes that are critical for early endosperm and embryo differentiation and development. It can be confidently predicted that this component of proteomics will be increasingly important in the future.

Metabolite Analysis

Metabolomics is the high throughput study of the complete complement of metabolites in a particular tissue under defined conditions. Its evolution is based on the argument that metabolite profiles are the ultimate reflection of gene expression at the biochemical level, and that metabolites are closer to cellular function than either mRNA transcripts or proteins. Examination of a cellular proteome might lead to the identification of several key metabolic enzymes, some of which would catalyze reactions at the branch points of biochemical pathways. However, flux down a particular pathway cannot easily be predicted from the relative abundance of the enzymes in the cell, because if one enzyme has a higher catalytic efficiency than another, it could preferentially direct metabolic traffic down one of the pathways. Metabolite profiles theoretically provide a more objective measure of the final metabolic activities of the cell. In the example of cereal cell wall biosynthesis, enzymes that catalyze sugar-nucleotide interconversions could control the biosynthesis of specific wall polysaccharides. An abundance of UDP-glucose dehydrogenase and UDP-glucuronic acid decarboxylase mRNAs or proteins might suggest that the cell is actively synthesizing UDP xylose and UDP arabinose for heteroxylan biosynthesis. However, the actual detection of high levels of the sugar nucleotides themselves in the cell would provide much stronger evidence that this was in fact the case.

Metabolite profiles are determined by extraction of the tissue with aqueous or organic solvents, components are separated by gas chromatography or liquid chromatography, and individual metabolites are identified through on-line mass spectrometric analysis and database searching. One expects to find at least 500 metabolites in the extracts, of which about half would be identified against libraries of mass spectra. Standardization of the extraction and separation procedures is critically important if meaningful comparisons are to be made between different tissues or different conditions. Furthermore, the technique generates large volumes of data, which are subjected to computer-assisted simplification through hierarchical cluster analysis and principal component analysis. There is accumulating evidence that plant cells possess a surprising level of plasticity that enables them to quickly compensate for changes in gene expression. Metabolomics technologies have the potential to define in detail the regulation of biochemical networks in response to changing environmental conditions.

Phenotype Analysis

The final element of functional genomics technologies to be briefly discussed here is phenomics, which refers to the high throughput measurement of defined phenotypic characteristics. This expensive process is being applied to the analysis of very large mutant populations of cereals, in particular rice. As the mutant plants grow, phenotypic properties – such as coleoptile growth rate, root mass and length, flowering time, nutrient uptake, leaf shape, and size – are recorded, often through automated procedures, and compared with phenotypes of wild-type plants grown concurrently. Mutants with interesting or anticipated phenotypes are subsequently subjected to other genomics technologies, such as transcript, proteome, and metabolite profiling, in an attempt to fully describe the function of the gene that has been mutated.

Functional Analysis Systems

An important requirement in any cereal functional genomics project is to develop a range of systems for functional analysis of genes. Given that putative functions can be assigned to fewer than half the genes discovered in plant genome sequencing projects, there is a good chance that many genes of interest in a cellular process will require detailed functional analysis. Even if the candidate genes can be tentatively identified through database searches, it is usually necessary to provide independent corroborating evidence for their function.

There are several approaches to functional analysis of genes discovered in genomics programs (Figure 3), although none are especially amenable to high throughput analyses. Perhaps the most direct method for defining gene function is through heterologous expression of cDNAs in bacterial, yeast, *Pichia pastorius*, and baculovirus systems, followed by the direct measurement of a functional activity. Thus, expressed enzymes can be analyzed for activity and specificity. However, technical difficulties with heterologous expression of high molecular mass or membrane-bound proteins, together with associated difficulties in obtaining correct folding of proteins in heterologous systems and the need for ancillary proteins for activity, will often limit the usefulness of this biochemical approach. In recognition of these difficulties, attention is being directed to the development of high throughput cell-free protein translation systems, in which a gene can be transcribed and translated *in vitro* to generate sufficient protein for assays and other analyses.

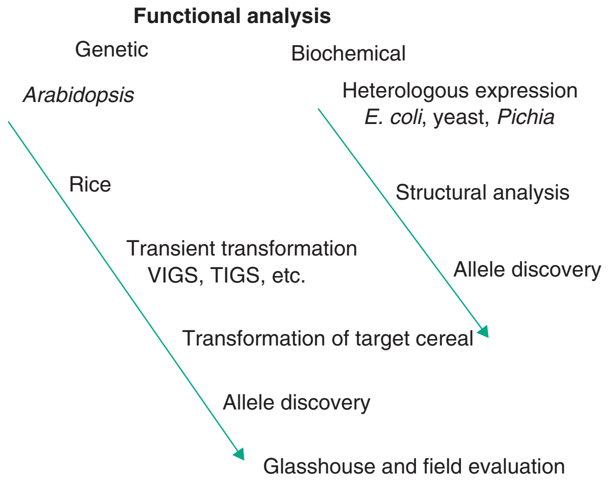

Figure 3 Functional analysis of candidate genes. Genetic approaches to functional analysis include loss-of-function and gain-of-function systems, through which genes are silenced or overexpressed, respectively. Silencing techniques include, *inter alia*, virus-induced gene silencing (VIGS), transiently induced gene silencing (TIGS), and stable transformation of cereals with the candidate gene. In the biochemical approach, candidate gene function is investigated through direct expression of the gene in a variety of possible heterologous systems. Subsequently, the 3D structure of the gene product and the degree of allelic diversity of the candidate gene can be addressed.

A second, genetic approach to the nonbiased functional analysis of a large number of genes is to generate mutant libraries, preferably through random insertion of T-DNA or transposons into many genes. The insertional mutagenesis approach results in a library of loss-of-function mutants. Because the sequence of the inserted DNA is known, the silence genes are "tagged" with a sequence from which flanking sequence can be readily determined. Thus, the gene that has been silenced can be identified in a mutant of interest. Several large transposon-tagged or T-DNA insertional libraries for rice have been generated and several groups are actively working on producing equivalent systems for wheat, barley, and maize. In maize, transposon-generated mutant populations have been widely used in gene identification projects. However, loss-of-function, or gene knockout, experiments can also be performed with selected genes of interest, at two levels. One method for functional analysis of candidate genes by loss-of-function is known as the double stranded RNA interference (dsRNAi) procedure. Here, dsRNAs with sequence identity with selected endogenous genes are introduced into single cells via microparticle bombardment and results of gene silencing can be observed quickly. Alternatively, the dsRNAi construct can be used to silence a targeted gene after its stable integration into transformed plants. Provided a measurable phenotype is observed, the procedure can be used to test the functions of candidate genes in functional genomics programs.

Loss-of-function systems have been open to criticism because they provide only indirect evidence for the role of a particular gene. Transgenesis can be accompanied by genetic rearrangements that could perturb expression patterns or indirectly silence expression through changes in genes encoding transcription factors. As a result, gain-of-function genetic systems for analyzing cereal genes by transgenesis into *Arabidopsis*, tobacco, and yeast might ultimately prove to be more useful, particularly where the genes of interest are not normally found in the other species. Alterations in phenotype would be used in screening assays prior to more detailed assays of gene function.

Economic, Social, and Environmental Benefits

A number of commercially relevant outputs can be expected from cereal functional genomics programs. First, novel genes will almost certainly be discovered and many will be valuable for crop improvement programs. The value of a novel gene will vary depending upon the significance of the altered phenotype resulting from transgenesis, the extent to which the phenotype will be modified, and the breadth of application. For example, a gene conferring efficient use of soil Mn in barley only, would be of limited value. However, a gene that stabilized yield under drought to provide an average 10% yield benefit over an extended period (an achievable goal) and was effective not only in wheat and barley but also in other crops would be highly valuable. Both genes and transgenic germplasm can be commercialized through delivery into breeding programs.

Where the gene controlling a trait has been isolated, diagnostic markers can be developed for each allelic variant of the gene (Figure 4). Such markers are 100% accurate in predicting the phenotype of the plants for the target trait and can be readily used in high throughput screening of germplasm in breeding programs. If, for example, a wheat marker tightly linked to drought tolerance were discovered, breeders in large wheat breeding programs would probably all wish to use that marker. Further, once a gene has been cloned, screening for allelic forms becomes possible and a range of alternative alleles could be identified. A diagnostic marker for specific alleles and the associated germplasm can be made available to breeding programs. It is also anticipated that functional genomics programs will develop new technologies

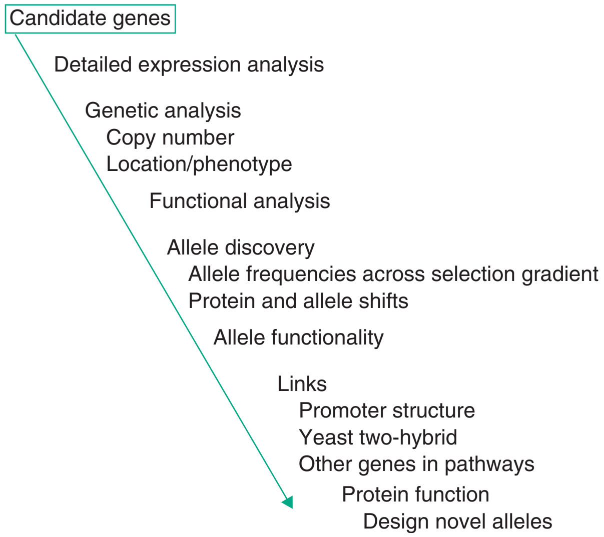

Figure 4 Additional analysis of candidate genes. Most cereal genes are members of multigene families. The number of genes and genome location of members can be defined, and the degree of allelic variation of individual genes can be investigated. In the latter approach, a gene of interest from different cereal varieties or related germplasm can be examined. If one variant of the gene can be associated with a trait of interest, such as tolerance to a particular abiotic stress, the effects of this variant, or allele, can be followed at the gene product and functional levels and, if necessary, transferred to other species or varieties. Further, interactions of the gene product of interest with other proteins in the cell can be identified through yeast two-hybrid technology and new alleles might be designed through a detailed knowledge of the structure of the gene product.

for gene and allele discovery and functional analysis of genes (Figure 4).

In most cereal functional genomics programs, the generation of products and technologies that can be quickly adopted by rural and related food and manufacturing industries will produce economic benefits in those industries. Let us consider potential benefits arising out of a genomics program on abiotic stress tolerance in the key cereals – wheat and barley. In Australia alone, the area sown to cereal crops in 2001 was close to 17 million hectares (Mha), and the value of those crops is in the $6–8 billion range annually. Functional genomics programs on abiotic stress tolerance could conceivably deliver an improvement of 10–20% in productivity levels if varieties with tolerance to multiple stresses could be generated.

Benefits accruing from the generation of plant varieties that are more sustainable, require less fertilizer, and have improved water-use efficiency and tolerance to salinity will extend beyond economic benefits to social and environmental benefits. For example, more than 50% of cereal cropping areas in southern Australia suffer regularly from transient salt stress, which is usually linked with moisture stress. Internationally, abiotic stresses represent the major cause of large yield fluctuations. It is estimated that wheat yields in India will drop to one-quarter of current levels by 2020 largely due to these problems. With the developing world accounting for almost half of the world's 550–600 million tons (Mt) annual wheat production, any improvement in yield stability under stress will have major social, economic, and environmental impacts internationally.

GLUTEN AND MODIFIED GLUTEN

I L Batey, Food Science Australia, North Ryde, NSW, Australia

What is Gluten?

A nontechnical definition of gluten describes it as "the sticky, viscous residue after removal of starch from flour." This definition would include corn gluten, the protein residue from isolation of starch from corn. However, this material is quite different to wheat gluten, the residue from production of wheat starch from flour. In the technical sense, the term "gluten" usually refers to wheat gluten. However, for people with food intolerance to cereals, especially celiac disease, "gluten" includes the equivalent proteins from rye, triticale, barley, and possibly oats (*see* **Celiac Disease**). Thus, "gluten-free foods" refer to food products free from these cereal proteins, or whose cereal protein content is less than a defined amount (usually 200 ppm). In this article, only the properties and uses of wheat gluten will be discussed.

Gluten may thus be defined technically as the "cohesive, visco-elastic proteinaceous material prepared as a by-product of the isolation of starch from wheat flour" (Figure 1). A more theoretical definition may define it as the "storage proteins of the wheat grain." Both definitions are correct but neither tells the whole story. For the purposes of this article, gluten is the commodity isolated on a commercial scale and sold for a variety of purposes in many countries of the world. In particular, the dry form of the product in which the functional properties may be regenerated by rehydration (a material known as "vital wheat gluten") will be mainly considered.

Figure 1 Gluten prepared from wheat flour, showing its cohesive and visco-elastic nature. (Courtesy of Colin Wrigley.)

Composition of Gluten

Although sold as a protein, gluten contains more than just protein. The commodity usually contains approximately 75% protein, 8% moisture, and varying amounts of starch, lipid, and fiber. The starch and fiber become entrapped in the cohesive matrix of the protein and become more difficult to remove as the protein content increases. The amount of starch varies, and more extensive washing can reduce the starch and fiber content and increase the protein content. The extra water needed for this creates its own problems by producing a larger amount of effluent from the process, and increasing the biological oxygen demand (BOD) of that effluent (see below). Consequently, gluten of higher protein content is only produced as a special order and at a premium price. Lipid is unaffected by additional washing. Most of the lipid content of the flour becomes associated with the protein during the washing process. The proteins are hydrophobic and the lipids bind to the hydrophobic areas of the protein as they are repelled by the water used in the washing. Lipids are strongly bound to gluten and are removed with much more difficulty than they are removed from the original flour. The lipid content of gluten is primarily determined by the lipid content of the flour from which it came, and is unaffected by additional washing.

The protein that makes up gluten is actually a complex mixture, containing many, perhaps several hundred, polypeptide species. A typical amino acid analysis of the complex mixture is shown in Table 1. The individual proteins are divided into two main classes – monomeric and polymeric. These terms can be confusing in that any protein is a polymer of amino acids. In gluten, monomeric refers to individual, discrete polypeptide species, whereas polymeric refers to chains formed from individual monomeric proteins by cross-linking them with disulfide bonds of cystine residues in adjoining chains. The monomeric proteins are often called gliadin and the polymeric ones are called glutenin. It should

be noted that some of the glutenin subunits do exist in gluten in the monomeric form (*see* **Wheat**: Grain Proteins and Flour Quality).

How Is Gluten Made?

Gluten was first prepared from flour almost 300 years ago by an Italian named Beccari, who conducted a simple water-washing experiment with wheat flour. This discovery, which can be easily reproduced in the home kitchen, has become the basis of a major cereal industry, utilizing millions of tons of wheat annually in North America, Europe, and Australia (Figure 2). The commercial process is basically an efficient repetition of Beccari's experiment. Most commercial operations use variations of either the "batter process" or the "Martin process."

Originally, gluten was produced as a by-product of the wheat starch industry. There is a high demand for starch for both food and nonfood uses, and in those areas where wheat was the major crop, it became the main raw material in the preparation of the starch required for various industrial purposes. Gluten became an embarrassing by-product. In some cases, its disposal was in municipal sewers and drains, but this soon became an undesirable practice. It was also dried in a variety of ways to yield a protein-rich material used in animal feeds, and wet gluten was also used to fortify bread and other baked products made from flour. The shelf life of wet gluten, usually only a few hours, severely restricted its use in this form. It was not until the application of ring drying that a dry vital gluten product could be prepared in significant amounts, allowing its trade as a valuable commodity.

Figure 2 Gluten prepared in a commercial process.

Martin Process

In this method, a wheat flour dough is washed with water while it passes through a tumbling cylindrical agitator. The work applied to the dough is not dissimilar to the effect of kneading a dough under water in that starch comes out of the dough and the protein content increases. The tumbling action moves the dough along the cylinder and the starch passes through small holes in the wall while the protein remains inside, receiving further washing until it tumbles out at the end.

Batter Process

In this process, a thick suspension or batter of flour is stirred slowly in a tank for several hours, during which time the starch separates from the protein. The mixture is then passed through a fine sieve, which allows the starch granules to pass through but retains the curds of gluten on the screen. This gluten is then washed with water to remove further starch in a similar manner to the Martin process and then dried.

The Martin process is a continuous process, while the nature of the batter process makes it more suited to batch operation.

Other Processes

Most commercial operators use one or other of the above methods with modifications, but there have been many other processes suggested for production

of gluten. While most have not made it past the laboratory curiosity stage, others, e.g., the Alfa-Laval Raisio process, have been applied in full-scale production facilities. The basis of these other processes varies and some use centrifugal techniques which may involve either conventional industrial centrifuges or hydro-cyclones to separate the starch from the protein. Many operators use hydro-cyclones as the principal way of cleaning the starch, and, in some cases, in the actual separation of the starch and gluten.

Many of the newer methods utilize whole grain as the raw material, avoiding the production of flour in a dry-milling step. This allows a more complete isolation of the starch fraction from the wheat, but cleaning the protein and starch of residual bran is a major disadvantage of these types of methods. Improved milling processes have reduced the amount of endosperm remaining in the bran and offal fractions in conventional milling, so there is little advantage to be gained in wet milling for starch and gluten recovery. There is also the need to dry the bran unless it can be processed on the spot or at least locally, and this cost will usually exceed the economic benefit of improved starch yield. Thus, despite these newer methods, modifications of the traditional processes have remained the preferred choice for almost all the gluten produced worldwide.

Dry Gluten

Gluten is very susceptible to heat when wet, and relatively low temperatures destroy the cohesive, visco-elastic properties ("vitality") which make it unique among food proteins. Attempts to dry gluten while retaining these properties were unsuccessful until the application of the ring drier to gluten in the first half of the twentieth century. This process has been the basis of gluten drying since then. The principle is that simple wet gluten with a moisture content of ~70% is mixed with sufficient dry gluten to reduce the moisture to ~20%. This lowered-moisture material is comminuted and subjected to flash drying in a ring drier. A portion of the dried gluten is removed and packaged, while the rest is returned to the drying cycle to reduce the moisture content of more wet gluten. The procedure is still very sensitive to excessive heat, but with careful control of the temperature a vital wheat gluten is produced.

An alternative way of drying to prepare a vital gluten is to disperse the gluten in aqueous ammonia or acetic acid and then spray-dry this dispersion. The resulting product retains the visco-elastic properties of gluten, and it may be used for most of the same purposes as normal vital gluten. The cost of this drying procedure, together with environmental concerns, limit its application except for special reasons. Another dry gluten product is known as "devital gluten." This material has lost its cohesive, viscoelastic properties, but retains the insolubility and water-binding capacity of vital gluten. It is commonly used where the cohesiveness of vital gluten can actually be a disadvantage.

Waste Products

The amount of water required for each ton of flour varies according to the operator. All processes have a significant waste stream which consists of the wash water plus soluble protein, damaged starch, and sugars plus some fiber. Disposal procedures for this waste vary, depending on the manufacturer, and methods include fermentation to produce ethanol or methane, isolation by drying for use in animal feed, and discharge into the sewerage system. The last option is becoming less common as environmental concerns grow worldwide.

Properties of Gluten

The most important properties of gluten are its solubility and its rheological functionality. By the nature of its preparation, gluten is a protein that is insoluble in water. While there are small amounts of water-soluble proteins trapped in the gluten matrix, these are essentially not extractable into water under normal conditions. Despite its insolubility and its hydrophobic nature, gluten absorbs approximately twice its dry weight of water to form a hydrated gluten. This material is effectively the same as the wet gluten first isolated from flour. In the case of commercially prepared gluten, drying conditions may cause some deterioration of the functional properties, but gluten prepared in the laboratory shows no change in its properties after freeze-drying and rehydration.

The principal components, gliadin and glutenin, are both insoluble in water. Gliadin can be solubilized in 70% ethanol, one of the steps of the Osborne fractionation of wheat proteins (*see* **Cereals**: Protein Chemistry) and the residue after this extraction is considered to be glutenin. Isolation of the dissolved material, however, yields a protein which has lost most of its functional properties. Both gliadin and glutenin may be solubilized to a certain degree by the use of acidic conditions. By careful control of the pH, gluten may be separated into a number of fractions. Reprecipitation by pH adjustment, or by drying the acidic solution directly, gives products which maintain their functional properties.

This can be shown by reconstituting flour through recombining the starch, the isolated protein fractions, and the water-soluble components prepared during the extraction of gluten. Doughs prepared by careful reconstitution show little change in dough strength compared to that of the original flours.

Its rheological properties are the basis of the functional uses of vital gluten. It is these properties that give wheat flour doughs the characteristics that allow the production of breads, cakes, biscuits, and noodles. Thus, gluten can be considered to be like a dough in which the diluting effect of starch is no longer present. In the wet state, the protein molecules form a cohesive matrix which, in dough, also holds the starch granules within it. This matrix is also elastic, allowing it to stretch and expand. In aerated doughs, this elasticity permits the expansion of gas bubbles which produce the texture of bread and cakes. If the gluten matrix is too weak, or the protein content is too low to form an effective matrix, the bubbles expand beyond the elastic limit and burst, reducing the overall volume of a baked product.

How Is Gluten Used?

The uses of gluten worldwide vary from country to country, but the most common usage in western countries is addition to flour in baked goods of various types (Table 2). The second largest use is in pet foods. Here, gluten is added as a protein source to improve the nutritional quality of the pet food. Its hydration and lipid-binding properties also assist in improving the overall properties of the product. A growing market for gluten is as an ingredient in aquaculture feed, where its cohesive properties hold the feed together when it is put into water.

Table 2 Usage of gluten in different regions (as percentage of total usage for region)

	N. America (%)	*EU (%)*	*Australia (%)*	*Japan (%)*	*Total world (%)*
Baking	83	16.5	54	30	63
Flour fortification	0.5	66	9		14
Pet food	12	13.5	13		8
Meats	1		9	25[a]	5
Breakfast cereals	1		12		2
Noodles				10	
Sausages				12	
Other	2.5	4	3	23	8

[a] Includes gluten used for synthetic fish products.

Gluten is used in other countries in a variety of ways. Perhaps the major use is as a meat replacement in vegetarian foods, and in the production of artificial forms of expensive foods such as crab meat. It is also used in the preparation of soy sauce extenders, and the manufacture of mono-sodium glutamate. The high glutamine content of gluten makes it an ideal starting material for this latter product.

Baked Goods

Wheat-based products, in which gluten is used to fortify flours of lower-than-desirable protein content, have been and continue to be the main application of gluten. There is a concern about the effects of gluten on people with celiac disease and others with wheat protein allergies, but its incorporation into foods that already contain gluten cannot be questioned. Increasing the protein content of a flour by adding vital gluten improves the quality of the flour to be equivalent to one with the higher protein content. This fortification may be necessary because the flour has a naturally low protein and a higher protein content is needed to make quality products, or because the addition of gluten provides a particular property sought in the food by improving the quality of the protein. Addition of gluten to a flour of low protein content improves the texture and shelf life of bread prepared from it, but it is useful in other applications as well. For example, addition of ~1% of gluten to flour reduces pretzel breakage in the finished product, but the addition of too much gluten may result in pretzels that are too hard to eat. Addition of gluten to pasta-type products will also reduce breakage. However, the desire of consumers for pasta of 100% durum wheat origin means that usage for this purpose is now more limited.

Other Uses

In addition to its use in pet foods, gluten is commonly added as a binder in meat products for human consumption. Here, the desired property is its ability to bind fat and water while at the same time increasing the protein content. Gluten and modified glutens have also been used in calf-milk replacements.

A number of nonfood uses have also been suggested for gluten. These include adhesives, paper coating, detergent formulations, slow-release pharmaceuticals, medical bandages, construction materials, and binding of heavy metals in industrial processes. Use of gluten in films has also been tried. Gluten-based films may be cast from solutions of gluten in ammonia. Production of gluten films with satisfactory properties could provide a new biodegradable film for widespread use.

Modifying Gluten

Gluten is a protein, intermediate in price between low-value commodities suitable only as animal feed without further processing and high-value materials such as casein and soy isolates. This gives significant scope for modification of its properties for value addition. Various threatened surpluses in the market for gluten have turned the attention of manufacturers to ways of converting gluten into products with vastly different properties.

Chemical Modification

The main modification applied to gluten is solubilization. Gluten becomes soluble in a variety of chemicals including urea solutions, lactic acid, soaps and detergents with or without urea, acetic acid, hydrochloric acid, sodium hydroxide, 70% ethanol, and 2-chloroethanol to name just some. Many of these are incompatible with food products, but for nonfood purposes there are few limitations other than cost, safety, and environmental concerns.

Solubilization by deamidation is the major method applied. This may be achieved with either acid or alkali. Approximately 90% of the glutamic acid in gluten is in the form of glutamine (Figure 3). Removal of the amide group of these residues to form the corresponding carboxylic acid changes the potential ionic charge on the protein, thus increasing its solubility above a certain pH. In acidic deamidation, there is also a degree of peptide hydrolysis to form lower-molecular-weight polypeptides which are also usually more soluble than larger ones. In alkali solutions, peptide hydrolysis does not usually occur as readily as in acid. However, there is the possibility of alkaline attack on the disulfide bonds of cystine, with the subsequent opportunity of creating cross-links due to the formation of lysinoalanine (Figure 3). Use of temperatures close to ambient has shown no formation of lysinoalanine. The reaction mixtures of acid or alkali deamidation require neutralization before the products can be used for their final purpose, a step which produces significant amounts of salts which usually need to be removed. This can be done by iso-electric precipitation, i.e., adjustment of the pH to the iso-electric point at which proteins are least soluble as they have no net charge. A procedure that uses acidic or basic proteins to neutralize the alkali or acid, respectively, has been reported. No inorganic salt is formed in this process, but the overall proportion of gluten in the final product is very much reduced. Deamidated gluten is easily dispersible which makes it suitable for use in foods for emulsification or foam stabilization. It has been used in meat products, nondairy coffee whiteners, beverages, and milk puddings. No benefits have been reported for the use of deamidated gluten in bread doughs.

Glutamine

$$\mathrm{HOOC\text{-}\overset{NH_2}{\overset{|}{CH}}\text{-}CH_2\text{-}CH_2\text{-}COOH}$$

Glutamic acid

$$\mathrm{HOOC\text{-}\overset{NH_2}{\overset{|}{CH}}\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}NH\text{-}CH_2\text{-}\overset{NH_2}{\overset{|}{CH}}\text{-}COOH}$$

Lysinoalanine

Figure 3 Structures of glutamine, glutamic acid, and lysinoalanine.

Gluten may be treated with sulfuric acid, phosphoric acid, or chlorosulfonic acid to prepare products which bind greatly increased amounts of water. There have been reports that some of these products bind up to 200 times their own weight of water. Other chemical modifications include acylation with carboxylic acid anhydrides. In particular, treatment of gluten with succinic anhydride increases its solubility at pH 7 (close to the point of minimum solubility of native gluten) but decreases its solubility at pH 3 where it is normally quite soluble.

Enzymic Modification

Hydrolysis of the peptide bonds by enzymes also increases the solubility of gluten. This is achieved by reducing the molecular weight of the polypeptide chains. A number of commercially available enzymes have been used for this purpose, including papain, bromelain, subtilisin, trypsin, and pronase. The enzyme-solubilized gluten has many of the properties of chemically deamidated gluten, such as foam stability and emulsion formation. Unlike deamidated gluten, enzyme-solubilized gluten has beneficial effects on dough properties. Addition at levels of 1–2% reduced dough mixing times by amounts similar to those achieved by chemicals, such as cysteine and ascorbic acid, which are often added commercially to give improved loaf volumes. Many of the reports of enzyme-solubilized gluten refer to it having a bitter taste. This is believed to arise from the formation of small peptides that have been identified with bitter flavors in other proteins. Thus, treatment with enzymes needs to be carefully controlled to minimize the formation of these small peptides.

The Future for Gluten

Production of gluten is still driven by the need for starch. Thus, it will always be produced while

wheat is a major source of starch. There is the risk that demand for starch will grow faster than the demand for gluten, but to date, this has not happened despite dire predictions on more than one occasion. Although its absolute price has not changed significantly over many years, by becoming relatively cheaper it has found its way into more applications for which it was formerly too expensive. This has served to maintain its value while output has greatly increased. Consumer concerns about gluten-free foods may limit its application in some areas, but the ubiquity of wheat in many foods ensures that gluten will remain an acceptable additive. The greatest threat to the gluten industry has been and will remain the lower cost of preparing starch from sources other than wheat. Gluten has played a major role in keeping the production of wheat starch economically viable in face of cheaper starch from other sources. This situation is expected to be unchanged in the future.

GRAIN, MORPHOLOGY OF INTERNAL STRUCTURE

H Corke, The University of Hong Kong, Hong Kong, People's Republic of China

This is a wide topic because virtually every aspect of grain technology is related to grain structure. Handling, processing, and utilization of grains depend on specific details of their structure. For example, in dry milling of rice and wheat, removal of the bran layers is necessary. The wheat grain is not covered with a tightly attached hull, so unlike in rice initial de-hulling is not required. Bran removal in wheat is part of the process of producing fine particulate flour by crushing the endosperm. Bran removal in rice should leave an unbroken polished rice grain. In both wheat and rice, endosperm should be at a specific hardness to achieve the desired outcome. Wet milling is a fractionation process. In maize, starch, oil, and protein components are separated. Again, the physical structure of the grain is exploited in the design of the milling process. Issues such as these will be covered in detail in this article. More specifically, the following aspects will be covered: wheat grain morphology and its effect on dry and wet milling; rice grain morphology and its effect on dry milling and nutrition; maize grain morphology and its effect on handling and wet milling; barley structure and its effect on brewing; and a comparative summary of general effects of grain structure.

Wheat Grain Morphology and Its Effect on Dry and Wet Milling

The relationship of the grain to overall spike structure is important in milling (Figure 1). Historically, the wheat ancestors (for example the diploid *Triticum monococcum*) had a brittle rachis trait. This means that after ripening of the grain and drying of the plant, the rachis (where the spikelet is attached to the axis) breaks naturally and the seed (still surrounded by a tightly bound palea, lemma, and awn) falls from the plant. This is an essential survival feature for a plant whose seeds are dispersed in nature through the action of wind, insects, etc. In a farmer's field, a brittle rachis would not be viable, as harvesting would be extremely difficult. The genetic step from brittle to nonbrittle rachis is the key to domestication of small-grain cereals (e.g., wheat, rice, barley). However, wheat has a further useful adaptation to domestication, which

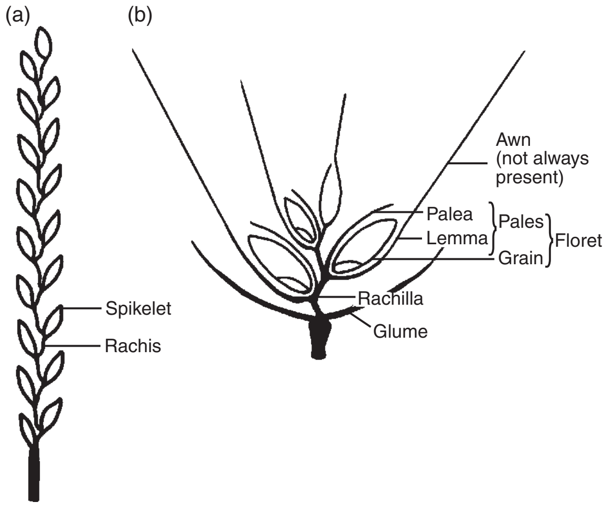

Figure 1 The structure of the wheat spike (ear). Cultivated wheat requires a nonbrittle rachis so that mechanical harvesting is possible, and a loosely attached palea and lemma, so that a dehulling step is not required. (From Evers AD and Bechtel DB (1988) Microscopic structure of the wheat grain. In: Pomeranz Y (ed.) *Wheat: Chemistry and Technology*, vol. 1, 3rd edn., pp. 47–95. St. Paul, MN: American Association of Cereal Chemists.

differs from rice. In wheat, the palea and lemma naturally separate from the grain – this is called a "naked" grain characteristic. In rice, the grain is "covered," i.e., the hull is attached to the grain and requires a separate processing stage (de-hulling) to remove it.

Bran

The wheat grain has been described as "a single-seeded fruit called a caryopsis, in which the ripened ovary wall is fused to the seed." The classical diagram for hexaploid common (bread) wheat (*Triticum aestivum*) grain structure was produced by the Wheat Flour Institute, Washington, DC (Figure 2). The objective of flour milling is to remove the embryo (germ) and the outer layers (epidermis, hypodermis, cross cells, tube cells, seedcoat, and nucellar tissue), which collectively are termed the bran. The aleurone layer, part of the endosperm, is also removed with the bran, and from a miller's point of view may be included as a bran layer. Much of the vitamin and mineral content of the grain is contained in the bran. In many countries, wheat flour is enriched or fortified to replace some of the nutrients lost in milling (*see* **Fortification of Grain-Based Foods**). Removal of the bran (which, including the aleurone layer, comprises ~15% of the grain by weight) permits production of white flour. Apart from appearance, white flour has different technological properties to whole-wheat meal (that produced by grinding the whole

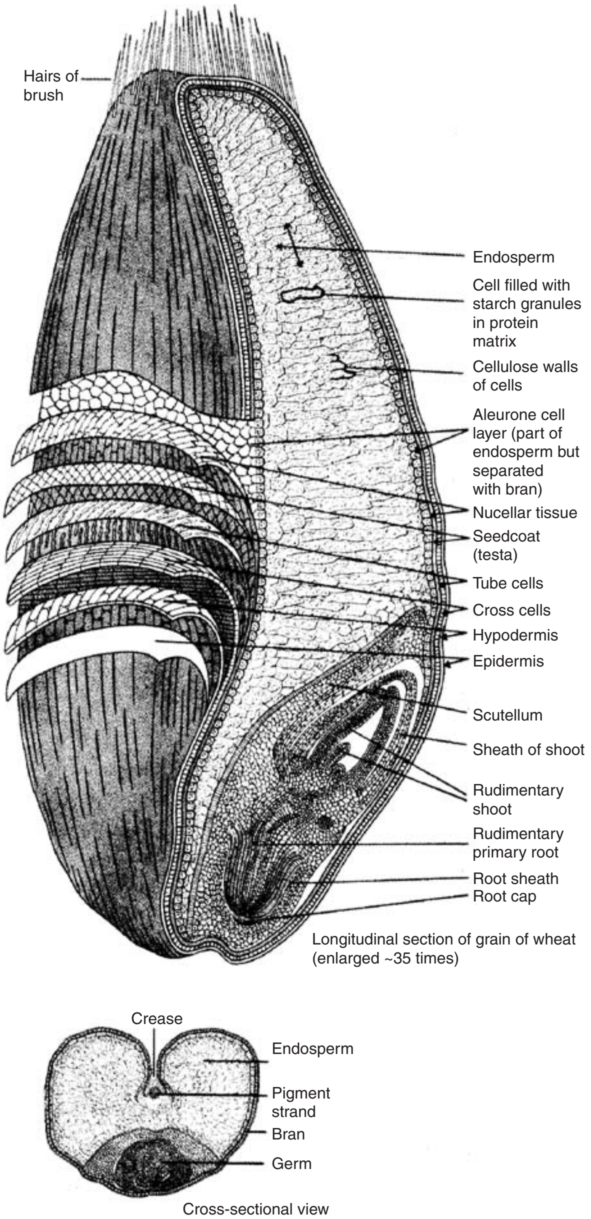

Figure 2 The structure of the wheat grain – longitudinal and cross-sectional views. (From Pomeranz Y (1987) *Modern Cereal Science and Technology*, pp. 25–39. Weinheim, Germany: VCH Publishers.)

grain without bran separation). The presence of large amounts of bran dilutes the proportion of gluten in the product, and results in a denser, more fiber-rich product. The presence of small amounts of bran (as bran specks) results in off-white color in flour and in many final products (e.g., steamed bread). In fresh white noodles, discoloration to gray is associated with polyphenoloxidase (PPO) content of flour, and most PPO is present in bran. In Chinese steamed bread, formation of brown spots on the surface may also be associated with PPO effects from bran

contamination (and the use of NaCl in the formulation). Because of the high mineral content of bran relative to endosperm, bran content in flour can be estimated by ashing (furnace heating) a flour sample, and weighing the residue. For the same flour yield, a variety that gives lower ash content (less bran) is of course preferable.

In wheat flour milling, grain is tempered to a uniform moisture content (usually 15.5%). The effect of this is to make the bran layers flexible so that under the crushing action of roller milling, bran will break into large flakes, not be crushed into powder. This formation of flakes of bran results in pieces, which are of different size, shape, and density to the endosperm particles, which on size reduction become flour particles. Without this physical flexibility in bran, milling would not be possible. However, with crushing, some endosperm is likely to be attached to some of the bran flakes. Continuing milling to remove the last particles of endosperm (i.e., aiming for a high flour yield, or percentage yield of flour relative to starting weight of grain) will increase contamination of flour with bran. The flour yield also depends on several other properties of bran:

1. the thickness of the bran layers, which is under genetic control,
2. the size of the grain – bran will be a relatively lower fraction of a larger grain; also a plump well-filled grain will be preferable, and
3. the characteristics of the crease.

The crease in a wheat grain is the lateral fold (**Figure 2**) ending with the pigment strand. A deep crease results in more problems with bran removal in milling – more bran particles attached to endosperm chunks usually result from a deep crease. Also, the crease can trap contaminants, e.g., dust and fungal spores, which can cause problems in storage and in cleaning the grain before milling.

Grain color in wheat, usually due to red pigmentation in the bran (seedcoat) is usually classified as red (presence of pigmentation) or white (absence). White wheat flour, if contaminated with bran, will show less discoloration than red wheat flour. This is why hard white type wheat is becoming more widely accepted as suitable for Asian noodles. Other colors are possible but rare in commercial trade – e.g., blue, purple, or even "black" wheat, with a dark purple pigment in the seedcoat, which is used in some specialty products in China.

Endosperm

The product of wheat dry milling is flour, the result of crushing endosperm. The endosperm consists of cells surrounded by a pentosan-rich cell wall (mostly arabinoxylans), and containing starch granules embedded in a protein matrix. The size of the cell and the thickness of the cell wall affect the proportion of cell-wall material relative to starch and protein in the endosperm. The cell wall absorbs water during dough mixing, so it is significant in determining optimum water absorption of a flour. The dimensions of the cell wall are genetically variable. The starch granules consist of two types, larger A granules and smaller B granules. Starch composition (proportion of amylose to amylopectin in starch) determines physical properties of any gelatinized starch product resulting from cooking the flour. This is most important in Japanese white-salted noodles ("udon") where a low amylose (partial waxy), high-swelling starch gives favorable texture. In many other products, such as baked bread, the starch composition, within normal limits for wheat flour, does not have much impact on product quality. Starch granules are subject to shear or breakage, termed "starch damage" in milling, if the endosperm is too hard (e.g., genetically hard texture, or too low moisture content in milling) or if milling equipment is not adjusted correctly. A broken granule, exposing the interior, is much more readily subject to hydrolysis by amylases during the bread-making process (during fermentation and early stages of baking before the enzyme is inactivated). Some starch damage may be desirable to provide a substrate for yeast growth, but excessive damage adversely impacts on quality and may result in a sticky texture in the final loaf. Endosperm hardness is largely due to the structure of two puroindolines (components of friabilin), which are amyloplast membrane proteins present in the endosperm. There is a widespread confusion about grain hardness (protein influenced) and noodle texture (starch influenced). A high-swelling starch but not necessarily a soft endosperm is required to make a soft-textured noodle (such as Japanese udon).

Embryo (Germ)

The embryo consists of the rudimentary structures (shoot and root) of the plant, which can grow from the grain, plus the root and shoot sheathes, the root cap and the scutellar tissue. The embryo, ~3% of the grain weight, contains ~8% of the grain protein, but it is mostly in the form of enzymes related to subsequent growth of the seedling, not storage protein (gluten) as in the endosperm. Thus, the wheat germ protein is of higher quality (more favorable amino acid balance, such as higher lysine content) for human nutrition. The lysine level in protein in the embryo is ~8%; in endosperm protein ~2%, and

in bran protein ~4.5%. In addition, 20% of the lipids of the grain are in the embryo (oil-containing spherosomes are present in the aleurone layer and in scutellar cells), but there are also high levels of lipase and lipoxygenase enzymes, which hydrolyze and oxidize oil, causing rancidity. Wheat germ hence has uses as a food material or supplement for human nutrition, and is valuable as an additive to animal feed (particularly for monogastric animals such as pigs and poultry). On the other hand, wheat germ, unless treated, has a short shelf life. Whole-wheat meal also has a shorter shelf life than white flour. Removal of germ to produce flour results in a product that is stable for long periods of time.

Other Features

Dry milling of durum (*Triticum durum*) wheat (a tetraploid species) to make semolina (larger particle size than flour from common wheat) has a few special features related to the durum endosperm texture. The physical hardness (vitreousness) of durum endosperm makes the grain liable to break during combine harvesting. These broken grains should be separated and recovered during cleaning of grain before milling, or a high level of wastage may occur. Optimum tempering of durum grain before milling is also essential, and varies with the vitreousness of the endosperm. Careful milling (e.g., more break rolls than for bread wheat) is needed to achieve suitably fine semolina for high-quality pasta.

In wheat wet milling (to produce wheat starch, gluten, and wheat germ oil), separation is by soaking the grain, crushing, and sedimenting off the starch component. B-type starch granules are too small to easily sediment and their complete removal would require expensive centrifugation steps. Hence, a genetically low proportion of B-type compared to A-type granules would be a strong advantage for increased starch yield in wet milling. Considerable effort is being expended to identify more suitable wheat varieties for this use.

Rice Grain Morphology and Its Effect on Dry Milling and Nutrition

Grain Structure

The anatomical structure of rice (Figure 3) is of course very similar to that of wheat. However, grain shape is

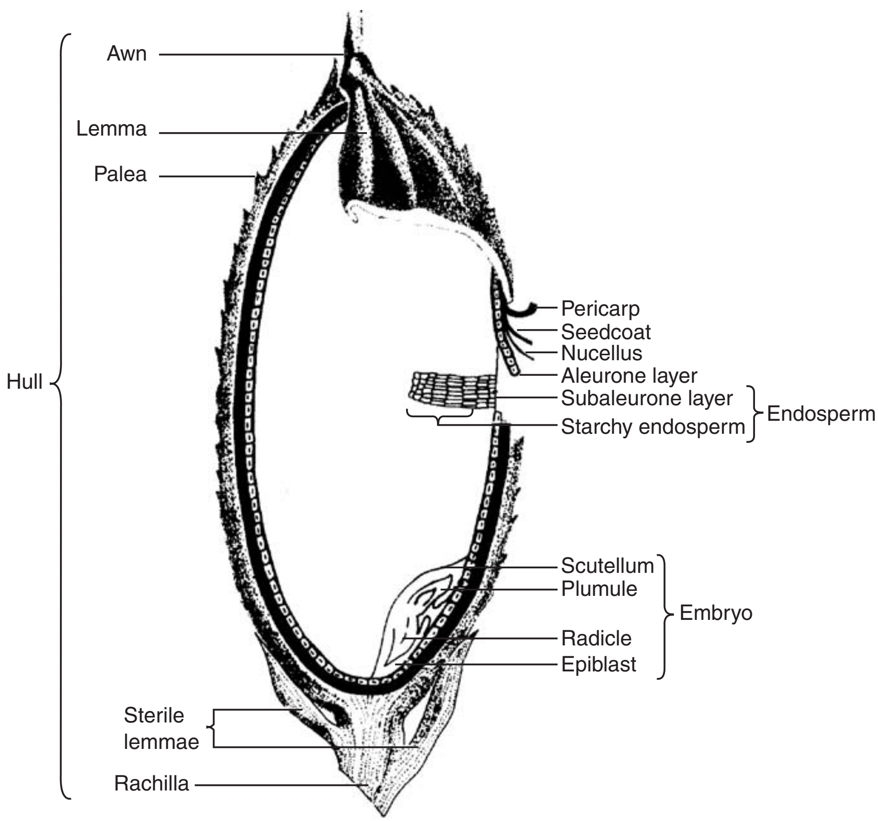

Figure 3 The structure of the rice grain (From Juliano, JB and Aldama MJ (1937) Morphology of *Oryza sativa* L. *Philippines Agriculturalist* 26: 1–134. Republished in Juliano BO (1993).

of more significance. Short-, medium-, and long-grain rice are common classifications. In the United States, texture can be recognized from grain length – short is low amylose (sticky) and long grain is intermediate amylose (20–25%) (harder cooked texture such that grains are separate after boiling). This is a marketing phenomenon, not a genetic relationship, and in other countries long grain may well be waxy or sticky types, sometimes a source of confusion to traveling Americans. Grain shape (expressed as ratio of length to width) affects milling. A rounded grain with a low length : width ratio will be more resistant to breakage than a slender type of grain. Rice lacks the crease found in wheat grains. This enables abrasive milling to remove the bran and leave only endosperm, greatly simplifying the milling process.

The hull, which covers the rough (also known as paddy) rice, comprises 17–24% of the weight of the paddy rice. It consists of lemma and palea, awn, the rachilla, and lemmae. Varietal differences in percentage of hull affect yield of brown rice, and this in turn affects milled rice recovery (yield of white polished rice). The hull (husk) is silica-rich and indigestible for human nutrition, even after heat treatment, even though it is rich in minerals.

Cracking

In producing polished white rice, the control of cracking is essential. Cracks caused by poor drying conditions after harvest, for example, will result in grain that breaks easily in milling (de-hulling or polishing) producing a lower yield of head rice and consequently much lower value product. In the production of parboiled rice, rice with the hull still attached is steamed, driving nutrients from the hull and the bran into the endosperm, inactivating enzymes that would cause rancidity, and reducing microbial load. However, after steaming, the parboiled rice must be dried slowly before it is de-hulled and polished, or cracks will form with the same effect as before. Parboiled rice, despite the steaming treatment, does not require less time to cook by the consumer than ordinary white rice, because water penetration to the center of the grain is slow. Instant rice is prepared by steaming polished white rice. It is dried rapidly, forming numerous internal cracks. These cracks, not the starch gelatinization induced by steaming, allow the product to be cooked by the consumer in a few minutes because they aid water penetration. Instant rice is more physically liable to breakage in transportation than raw polished white rice, and the softer texture resulting from the cracks is unattractive to traditional rice consumers in many parts of the world.

Rice Bran Layers

The bran layers (pericarp, seedcoat, nucellus, and aleurone layer) contain most of the minerals (represented as ash), vitamins, fiber, fat, and much of the protein present in the rice grain (Figure 4). Considerable debate over the years has taken place over the suitability of white polished rice, compared to brown rice, in nutritionally deficient diets in some developing nations. In fact, bran also contains phytate (phytic acid), which binds to available minerals provided by brown rice, and may also bind and remove additional minerals from the gastrointestinal tract. Brown rice consumption may therefore cause a net loss of minerals to the body, and in addition is susceptible to rancidity in storage (lipids and lipases still present) and more susceptible than polished rice to storage pest attack.

Rice Endosperm

Rice starch granules are small (2–4 μm), polygonal and compound, i.e., many small granules are compacted together. Compositionally, rice starch varies from 0% (waxy, sticky, glutinous) amylose to over 35%. This range is much wider than found naturally in hexaploid wheat starch. Expression of naturally occurring waxy mutants is more likely in a diploid cereal (e.g., rice, maize, sorghum) than in a hexaploid

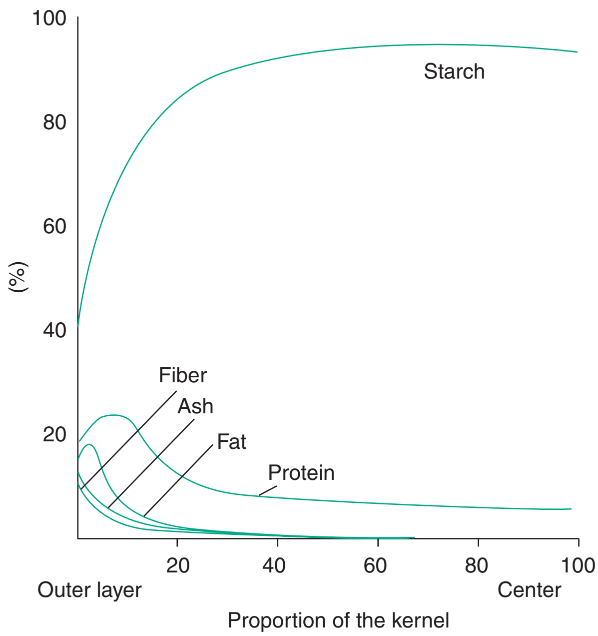

Figure 4 The effect of progressive surface abrasion of brown rice on content of major constituents. (From Barber S (1972) Milled rice and changes during aging. In: Houston DF (ed.) *Rice: Chemistry and Technology*, pp. 215–263. St. Paul, MN: American Association of Cereal Chemists. Republished in Juliano BO (1993).)

where effect is buffered by the other two sets of chromosomes present. Rice differs from wheat and maize in having crystalline protein bodies rich in glutelin, in addition to the prolamin-rich protein bodies common to all cereal endosperms (Figure 5). The aleurone layer (considered here as botanically part of the endosperm, although it is processed as part of the bran) differs in thickness (usually 1–7 cell layers) depending on variety. The aleurone cells contain protein bodies and lipid bodies.

Rice Embryo

The rice embryo is smaller relative to the whole grain than in wheat. It contains several types of parenchymatous cells, containing protein bodies and/or lipid bodies. The main parts of the embryo are the cotyledon and the embryonic axis. The plumule and radicle are similar to other cereal grains. The high lipid content of the embryo contributes to susceptibility to rancidity in storage of brown rice.

Maize Grain Morphology and Its Effect on Handling and Wet Milling

Maize is monoecious, having separate male and female flowering parts on the same plant. The female seed-bearing part of the plant (called the ear) develops off the lower-middle side of the plant and consists of a central cob with ~800 seeds attached in rows by the pedicel, and covered by a husk. The pedicel acts as a conduit for photosynthetic products supplying the developing grain. The male part of the flower – the tassel – produces pollen and is at the top of the plant. The maize grain (Figure 6) is ~10 times larger than small-grain cereals, an average dent maize grain weighing ~300 mg. The flattened sides of the mature grain are due to pressure from the tight packing in rows on the cob. After removal of the husk, the maize grain is exposed ("naked" characteristic) and easily separated from the cob.

Handling

Shelled maize grain (grain separated from the cob and packed in bulk) is more likely than other grains to enter export markets. A high proportion of the US maize harvest is exported, often to highly quality-conscious markets such as Japan. A typical export grain may enter the transportation system by traveling by barge down the Mississippi, entering the Gulf of Mexico for the long voyage to Asian markets. This is physically stressful on the grain, and a poorly dried grain with internal cracks is liable to breakage. This contributes to quality loss and increased susceptibility to insect or fungal attack and moisture damage. The primary criterion for successful shipment of maize is suitable endosperm texture (hard enough) and suitably controlled harvesting and drying to avoid cracking.

Wet Milling

Most maize which is not fed to animals is processed by wet milling to produce starch (with many diverse applications, such as further processing high fructose corn syrup, fuel alcohol, or modified starch for food and nonfood industries); oil (a high-quality cooking oil); and protein or fiber-rich fractions which are used in livestock feed (*see* **Maize:** Wet Milling). The composition of these components in the grain is of course of the utmost importance. As the maize seed is much larger than wheat or rice, the relative proportion by weight taken up by the bran layers (including aleurone layer) (~5%) is less than in these other cereals.

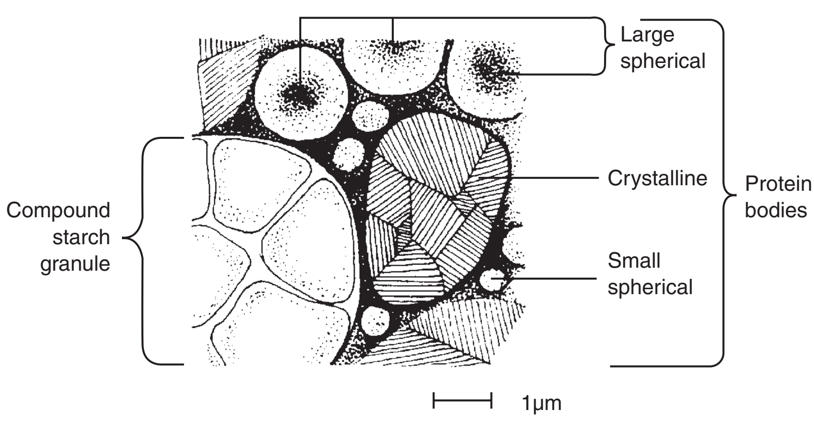

Figure 5 The rice endosperm indicating structure of spherical and crystalline protein bodies. (From Coffman WR and Juliano BO (1987) Rice. In: Olson RA (ed.) *Nutritional Quality of Cereal Grains*: *Genetic and Agronomic Improvement.* Madison, WI: Agronomy Society of America. Republished in Juliano BO (1993).)

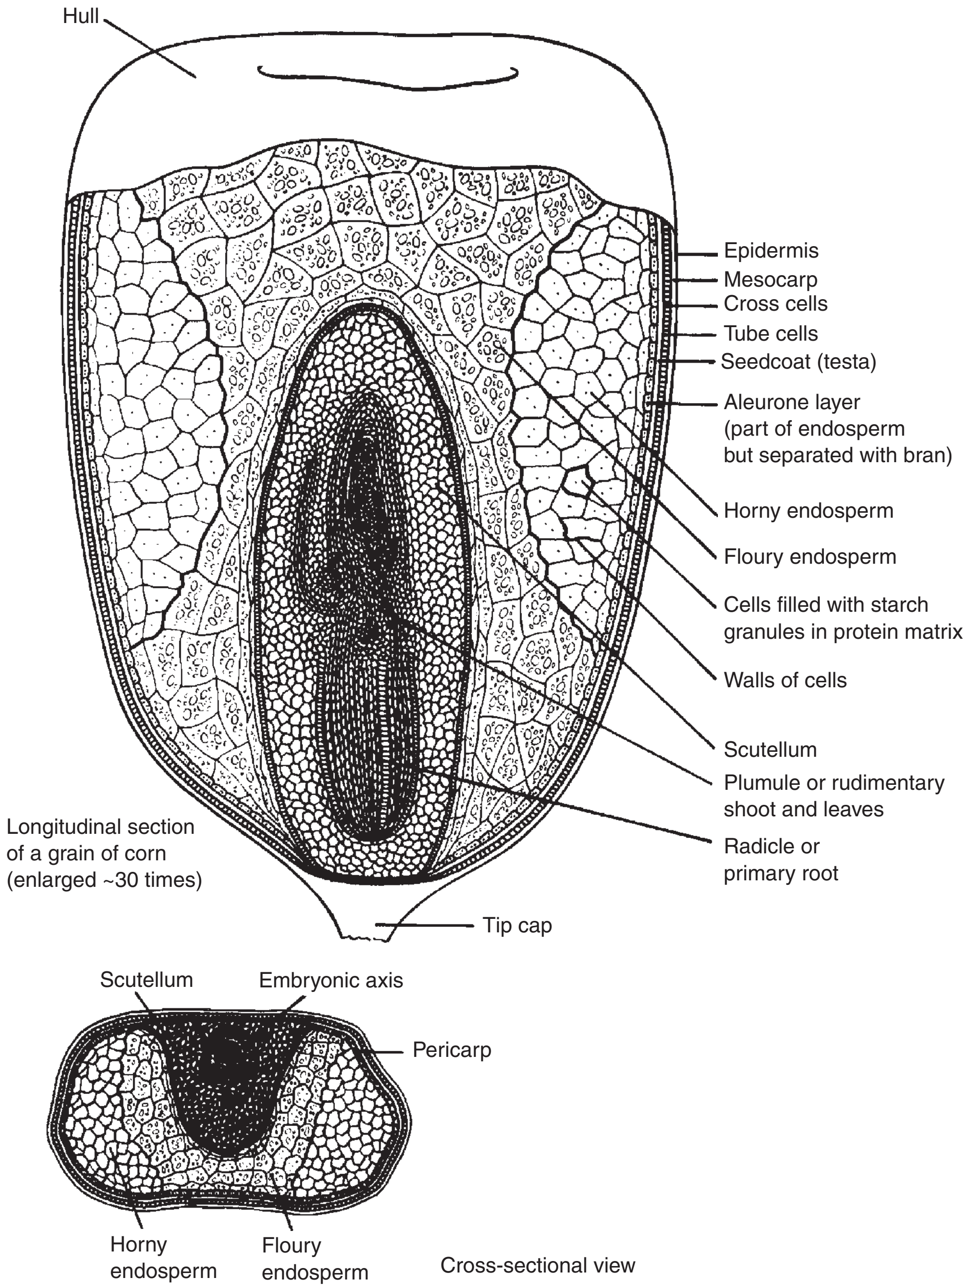

Figure 6 The structure of the maize grain – longitudinal and cross-sectional views. (From Pomeranz Y (1987) *Modern Cereal Science and Technology*, pp. 25–39. Weinheim, Germany: VCH Publishers.)

The embryo of maize is a much higher proportion of the grain (~11%, containing ~33% of the oil) than in other cereals; hence, the overall oil content of the grain is quite high (typically 5%). Also, a higher proportion of the total protein is nonstorage in nature (e.g., enzymes of the embryo), so overall the protein of maize is higher quality for human nutrition than that of wheat flour. However, maize protein, like other cereals, is deficient in lysine. High-lysine mutants (*opaque*-2) give more favorable amino acid balance suitable for feeding people or monogastric animals even without additional protein sources (*see* **Maize**: Genetics; Breeding). In practice, spread of *opaque*-2 varieties has been limited because in most cases production of normal endosperm maize, and supplementation with soy protein, is easier for animal feed production. Similarly, a classic long-term selection experiment at the University of Illinois showed that the oil content of maize could be increased to extremes of over 40%. This was basically a result of increased embryo size relative to endosperm.

The maize endosperm, the source of starch and most of the protein, has several interesting features. Maize types are classified by endosperm hardness. "Floury" is a soft endosperm that can be easily crushed to a friable powder. It is physically susceptible to storage pest (mainly insect) and fungal attack. An example of floury maize is the *opaque*-2 mutant. "Dent" has a high proportion of floury endosperm but some horny or hard endosperm (Figure 6), and is the most widely produced commercial maize. The "dent" refers to the indentation at the top of the grain on drying when it contracts due to the floury endosperm component. "Flint" maize (of which popcorn is one special type) has only horny and no floury endosperm. The top of the seed is rounded, not indented, and it is physically very hard, even after cooking meal prepared from it.

The outer layers of maize (the seedcoat in particular) contribute the color, which is white or yellow in nearly all commercial maize production. Mass production of maize for feed and industrial use, for example in the US, is predominantly yellow dent. Some white dent is produced for breakfast cereal (e.g., corn flake) production (which follows maize dry milling). The carotenoids (xanthophylls) of yellow maize are nutritionally important and also, in poultry feed, contribute yellow color to egg yolks and to skin and fat of meat poultry. People in regions where maize is a daily food staple may have strong color preferences, e.g., in southern Africa, white (dent) maize is strongly preferred because yellow maize is historically associated with flintiness (although there is no genetic relationship).

Maize Dry Milling

This also requires a physically sound clean sample with appropriate hardness. Dry milling in the US usually implies use of white maize (a minor proportion of total US production) to make endosperm chunks, which may be steamed and flaked to make corn flakes. Larger dry milling industries exist to serve the needs of maize tortilla production (Mexico) and maize porridge production (a staple diet in much of sub-Saharan Africa) requiring maize meal.

Barley Grain Structure and Effect on Malting

The barley grain is similar in structure to the wheat grain. For a diagram and further information on this topic, *see* **Barley**: Malting and **Beverages**: Distilled.

Overview

The same principles apply when considering the structure and utilization of other grains, such as sorghum, millets, oats, or even the pseudocereals buckwheat and *Amaranthus*. First consideration should be the required product, flour, separation of starch/protein/oil, or malt, which drives the choice of process – wet or dry milling, or malting. The size and shape of the grain, particularly the dimensions of the outer layers will most affect dry milling. In some cases, the seed is extremely small (e.g., with *Amaranthus*) and dry-milling flour yield will be low. For such crops, selection for larger grain size can greatly increase flour yield. For wet milling, the fraction of most value (usually starch) will drive the design of the separation process. Usually the starch–protein binding needs to be loosened by soaking in a solution, such as in alkaline wet milling, where the physical properties of the starch may be affected. Care should be taken that the fractions separated still achieve proper functionality in the intended use.

GRAINS AND PLANTS, MORPHOLOGY

R J Jarman, NIAB, Cambridge, UK

Introduction

The recognition and specific identification of food and ornamental plants from the morphology of the grains, seeds, and the whole plant still has an important economic role. It is often the main method used to monitor and control the ownership of new varieties of crop plants for Plant Breeders Rights (PBR) and the seed quality as a guarantee of consumer protection.

The methods used follow the basic principles of plant taxonomy and the classification of the plant kingdom established by Linnaeus and subsequent systematic botanists. The study of morphology is used mostly to identify varieties (also called cultivars) which are the lowest known groupings within a single botanical unit after species and subspecies and are the products of plant breeding.

A variety is:

- defined by the (physical) expression of the characteristics resulting from a given genotype or combination of genotypes;
- distinguished from any other plant grouping by the expression of at least one of the said characteristics; and
- considered as a unit with regard to its suitability for being propagated unchanged.

Performance characteristics such as yield or malting or bread-making quality have not been used to define varieties because they are affected by the growing environment and are not capable of precise description. Some would describe the use of morphology of the plant and seed as a traditional method, based on the detailed recognition of botanical structures used by experts, who have developed their own personal experience over many years of practice. Recently the principles of morphological examination have been adapted into more modern methods using digital image analysis that captures, stores, measures, and then analyzes plant structures using computer technology. However, the great advantage of identifying plants from their morphological characteristics is that it is cheap and easy to use and the necessary skills can be quickly learnt. These skills can also be easily applied wherever varieties are being purified, entered for variety registration, or traded commercially using little more than a $\times 10$ to $\times 20$ handlens.

Increasingly, the use of morphological characters supports other techniques of plant identification such as DNA technologies and protein electrophoresis. This is because the expression of morphological characteristics is influenced by the local environment in which the plant grows, whereas the expression of molecular and biochemical traits is not. Their expression is independent of the growing environment and therefore much more consistent. The disadvantage of these newer techniques is that they can be more expensive to perform and often require considerable expertise. However, test kits for DNA analyses are becoming more portable and could offer the most accurate method yet for plant identification.

Historical Background

Breeding new plant varieties by consciously selecting those with improved yield (agricultural crops) or with more ornate flowers (ornamental and horticultural

crops) has been taking place for about 150 years. At Debenham in Suffolk, England, in 1825, the Reverend John Chevalier was attracted to the "fine appearance" of the ears of barley growing from the gleanings gathered after harvest in the yard of a farm laborer. It became the variety Chevalier and it was grown widely for malting in England up to the 1930s. Its morphology was distinctive. It had narrow ears that bent over when ripe and the rachilla, the segment of the rachis that remains attached to the grain, had short curly hairs. Chevalier remained true to its description throughout its commercial life. The cultivation of Chevalier was resurrected in 1999 to produce malt for traditional ale to celebrate the millennium.

Bere barley, an ancient landrace, probably brought to Britain during the eighth century by the Viking colonists from Scandinavia, is still grown in Scotland today. It is one of the world's oldest surviving varieties and, as far as we can tell from historical accounts, still retains its unique and distinctive morphology (Figure 1).

Although the morphology of agricultural plants is incidental to characteristics such as yield and disease resistance, it has proved possible to describe the morphological characters of new varieties so they can be accurately recognized and maintained as discrete and unique units.

From the 1940s to the 1960s, a great deal of work was carried out in Europe, North America, and Australia describing the characters of new varieties. The objective was to offer farmers some guarantee that the new varieties they purchased were true to variety and that their agronomic performance, especially yield, would meet the claims made by plant breeders and seed merchants.

There were problems, however. In the rush to improve agricultural productivity and achieve self-sufficiency, there was a proliferation of varieties with "synonyms" (using different names for the

1523 Fitzherbert: *Boke of husbandry*: described three types of barley

- "Sprott-barley," Spratt or battledore barley, a two-row barley with very broad ears.
- "Longe-eare barley" – a general term covering three recognizable two-row barleys with long lax ears: "rath" (early) ripe, "meddle" (middle) ripe, and "late" ripe barleys.
- "Beare barley" – a six-row barley still grown in Scotland and the Orkney Islands in the UK.

These were all *spring* sown.

1757 Lisle: *Observations in Husbandry*: also described three types of barley

Early ripe Middle ripe Late ripe

Chevalier Archer × Spratt Plumage (Danish) × Archer (1905)

same variety) and "homonyms" (using the same name for different varieties). There was little incentive for private plant breeding because new varieties and seed could be "pirated" and renamed. Most of the breeding for arable crop species was carried out under government subsidy because it was unprofitable. There was no agreed system to define and describe new varieties using morphological characters.

UPOV and PBR

To address this situation, the International Union for the Protection of New Varieties of Plants (Union Internationale pour la Protection des Obtentions Vegetales (UPOV)) was established in 1961. This convention adopted an international basis for the award of PBR (also called Plant Variety Rights) and agreed guidelines for the conduct of tests and the standardization of variety descriptions based upon the morphology of the grain and plant. PBR is an intellectual property right, often described as a plant "patent."

UPOV's mission is to promote an effective system of plant variety protection with the aim of encouraging the development of new varieties of plants for the benefit of society. PBR enables plant breeders to claim royalties on seed sold to recover profits and breeding costs to reinvest. Once granted, PBR gives the holder exclusive marketing rights and control over a variety's reproduction for sale. PBR has proved to be a profitable incentive to plant breeders, and hence most plant breeding is now carried out by commercial companies.

In the UK, new and improved varieties have contributed to yield improvements of up to 1–2% per year and the cost of royalties to a cereal grower, breeders claim, represents less than 2% of the total input costs. Royalties on a successful winter wheat variety may be worth up to \$2–5 million per year and the commercial life of a variety at this level of royalty return is ~5 years, although some varieties are widely grown throughout the entire period of the Rights which expires after 20 years.

The key to PBR is the production of a variety description which describes the morphology of the protected variety using characteristics of the plant and grain.

The morphology of plant and grain is important in the following ways:

- the award of PBR and tests for distinctness, uniformity and stability (DUS);
- the control of seed production by certification to ensure seed sold for agricultural production is true to the variety it is claimed to be; and
- the control of variety purity at the point of final sale, e.g., from the farm to the food processor.

Tests for DUS

Rights are granted by growing plants in field and laboratory tests to describe the morphology. To be awarded PBR, a new plant variety must be:

- novel – new to the market, i.e., not available commercially usually before the date of application for DUS tests;
- distinct – have a unique identity;
- uniform – must be sufficiently uniform within the limits achievable of the species breeding system, e.g., self-pollinating or partially out-pollinating or obligate out-pollinating etc., from which the new variety was derived; and
- stable – capable of reproducing its uniqueness and uniformity over successive generations.

DUS tests take place mainly in field-sown plots, usually over two successive growing seasons. During this period the morphological characters on plants and seeds are recorded. The UPOV guidelines specify which characters should be recorded, at what growth stage records should be taken, the states of expression of individual characters, and example varieties that illustrate specific states of expression (Figure 2).

For the self-pollinating cereals, recording characters is straightforward. Repeated self-pollination after the F2 generation reduces the amount of segregation by half in each successive generation so that at F8 the new variety becomes closely homozygous. At F8 the new variety is usually entered into DUS tests and performance trials (Figure 3). The expression of the morphological characters at this stage is mostly consistent and uniform and failures for lack of uniformity occur in ~5–10% of new applications. Distinctness is measured by recording the morphological characters on a 1–9 scale of expression: one represents the state of expression at its weakest value, nine represents the strongest state of expression. UPOV calls these scores "notes." For example, anthocyanin color of the awn tips in barley is recorded as 1 = absent to very weak, 3 = weak, 5 = medium, 7 = strong, 9 = very strong.

For all the small-grained cereals – wheat, barley, and oats – there are a small group of characters that show discrete differences of expression rather than a continuous range of expression. In barley the rachilla, a vestigial extension of the main stem that is retained on the grain, has either short curly hairs or long silky hairs. The variety Chevalier was distinctive in having a short-haired rachilla, whereas the

Year	*Generation*		*Selection*
1	Initial cross	Malting quality × disease resistance	Choice of parents often based upon existing varieties that are commercially successful
2	F1	|	
3	F2	2000 single plants	Selection for disease resistance by deliberate infection
4	F3 and F4	100 lines from selected plants	F4 grown in Australia/New Zealand to achieve two generations in one harvest year; micromalting selection tests
5	F5	8 lines from selected plants	Replicated yield trials, malting tests, purification using morphology and protein electrophoresis
6	F6	4 lines	Further yield trials; purification using morphology
7	F7	Plants from lines harvested and grown as plant or ear rows; harvested seed bulked	Final breeders performance evaluation trials; purification by morphology/protein electrophoresis; seed bulked for official tests and trials
8	F8	First year of official tests and trials	Purification based on morphology to prepare seed for commercial seed production
9		Second year of official tests and trials	Preliminary certification for seed production; purification based on morphology
10		Award of PBR; listed for marketing	Enters commercial seed production and official seed certification
11		Further commercial evaluations for marketing	Limited seed available to farmers
12		Final commercial evaluations for marketing	Seed widely available to meet demand from farmers for new improved variety

Figure 3 Simplified UK cereal variety breeding scheme.

majority of barley varieties grown worldwide have a long-haired rachilla (Figure 4). In wheat there is a similar discrete difference in varieties that have scurs, slender bristle-like projections from the glumes and lemmas that encase the grains and others that do not (Figure 5).

To establish distinctness a profile of morphological characteristics of the plant and grain is recorded. This process records morphological characters from early growth habit of the juvenile plant to characters of the grain at harvest ripeness. This profile is then compared with all other varieties. A consistent difference

Figure 4 Differences in barley rachilla hair type: left, long-haired; right, short-haired. (Illustration published with permission of NIAB.)

Figure 5 Differences in scurs of wheat: left, scurs absent; right, scurs present. (Illustration published with permission of NIAB.)

of at least 1 scale point from the most similar variety is usually enough to confer distinctness. However, each character used to establish distinctness and listed in the final variety description must also show uniformity and stability of expression over the testing period.

The weakness of the UPOV methods using morphological characteristics is that some characters show a continuous range of expression that can vary according to the local environment in which a variety is grown. UPOV provides an international and harmonized DUS testing system but the same variety grown in a range of UPOV member countries may vary by as much as individual varieties.

The Characters Used to Describe Cereal Plants and Grains

The following morphological characters apply to the small-grained cereals – wheat, barley, and oats – but can also be applied to most other cereal species.

Seasonal Type

There is a physiological division of the major cereal grain crops, wheat and barley, into winter and spring varieties. Winter-sown varieties require a period of cold weather to trigger the development of meristems that will produce flowers whereas spring varieties do not.

Early Growth Characters

Early growth characteristics of these two seasonal types can be distinctive. Winter varieties show a prostrate early growth habit and spring varieties have a much more erect growth habit. Individual varieties can show extreme ranges of expression. Winter varieties of barley and oats have distinctive erect hairs on the lower leaf sheath, whereas spring varieties do not. These characters are probably not related to seasonal adaptation but are the result of the heritage of their parent varieties.

In wheat, the anthocyanin color of the coleoptile of 1 week old seedlings is a useful morphological discriminator.

Leaf Characters

Characters such as leaf color, size, and leaf attitude may also be distinctive in early growth stages. Six-row barleys typically have broad fleshy leaves and a higher leaf area index that may contribute to the higher level of photosynthetic activity that results in higher grain yields compared to two-row barleys. In northern Europe, all wheat varieties have auricles – the small claw-like structures that clasp the stem at the junction of the leaf blade and the leaf sheath – with small hairs; some North American and Australian wheat varieties do not. Barleys do not have hairy auricles and in Europe this is a useful way of distinguishing wheat and barley at the juvenile growth stages before ear emergence.

Ear Emergence

The appearance of the ears or panicles as they burst out of the flag leaf sheath in 50% of visible tillers defines ear emergence and is a valuable character that distinguishes many varieties. To an experienced observer a difference of 2 days is enough to identify closely similar varieties. Anthesis is closely linked to ear emergence and in wheat most varieties have

Figure 6 Side-by-side plots of two different barley varieties showing differences in ear emergence: left, ears emerged; right, ears not yet emerged. (Illustration published with permission of NIAB.)

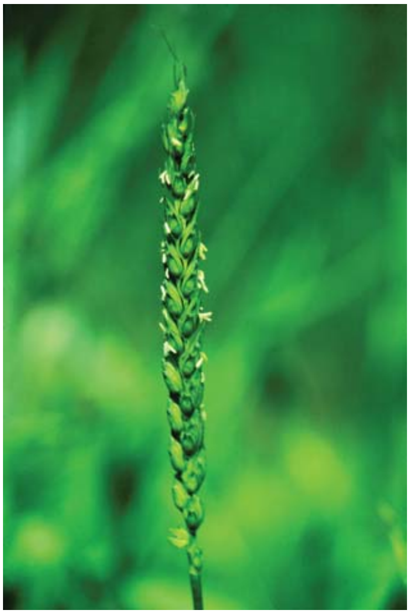

Figure 7 Wheat ear at anthesis with yellow-colored anthers. (Illustration published with permission of NIAB.)

yellow-colored anthers but some have red anthers (Figures 6 and 7).

Plant Height

This is an important discriminating character. Some varieties have been bred to express dwarf characteristics but are often oversensitive to growth factors such as temporary drought; others are too tall, especially in response to applications of standard dressings of nitrogen fertilizers and the stems buckle reducing harvest yield. A repeatable difference of 5–10 cm in height can be enough to differentiate varieties.

Glaucosity

From ear emergence onwards many cereals develop a waxy "bloom" that covers the leaves and inflorescences. Glaucosity appears as a layer of exuded wax particles that coat the surfaces of the plant. It is probably a residual adaptive characteristic that prevents water loss. Some wheat varieties are very strongly glaucous with a heavy blue-gray waxy covering over the leaves and all the floral bracts. Other varieties can be distinguished by the varying degrees of glaucosity on the leaves, the exposed neck, or culm of the tiller and the ears. Some varieties have no glaucosity at all which gives the crop a distinctive clear bright green appearance. Glaucosity characteristics are valuable in identifying contamination with other varieties. They are easily recognized at ear emergence and 10–14 days after ear emergence and are used by plant breeders and seed producers to purify crops or lines that are to be submitted for official test and trials. Glaucosity characters are fickle and are easily lost in windy conditions; as plants rub together the wax is rubbed off.

Anthocyanin Pigmentation

In barley the lower leaf sheaths, the auricles, the tips of the awns and the nerves on the ripe grains may either show presence or absence of pigment or show varying degrees of pigmentation when it is present. These are useful discriminating characters but the degree of pigmentation is affected by the environment within crops, between crops, and between years of the same variety. Wheat pigmentation, when present, is confined to the auricles and in some varieties from North America and northern Russia it is present in the awns.

The Morphology of the Ear

Fully developed ears of the major cereals crops show a range of characters (Figure 8). Ear length, the density or compactness of grains on the ear, the attitude of the ear, and the presence or absence of awns and scurs are important morphological features. In barley a major division is either six-row or two-row varieties. Both types are treated as *Hordeum vulgare* L. but in six-row varieties all the florets produce a viable grain whereas in two-row barley only the median grains are viable. In two-row barley the size and attitude of the sterile spikelets is a useful character (Figure 9).

Figure 8 Differences in the "collar" of the first rachis segment of barley ears: left, "platform" collar; right, "cup" collar. (Illustration published with permission of NIAB.)

Figure 9 Differences in the attitude of the sterile spikelets of two-row barley: left, sterile spikelets divergent; right, sterile spikelets parallel. (Illustration published with permission of NIAB.)

The most important characters are those associated with the small bracts that enclose the grains: glumes, lemma, and palea. The high-protein North American bread wheats are typically red chaffed – these floral bracts become reddish brown at maturity – whereas in Europe they are whitish. In some oats the lemmas and paleas that tightly enclose the kernel of the grain can be black, brown, gray, white, or yellow, each state is discrete and diagnostic. In wheat the internal and external characteristics of the glumes are very important. Identification is based on a combination of individual structural features such as width of the glume shoulder, shoulder

Figure 10 Contrasting shapes of the lower glume of wheat.

shape and shoulder length, length and curvature of the beak, and degree of hairiness of the internal surface. Many experts could extend this list of characters. For example, in the UK the structures of the glume have been used to support forensic evidence in a murder enquiry. Glume characteristics can be used with confidence from ear emergence to harvest ripeness (Figure 10).

Morphology of the Grain

In many grasses such as wheat, the lemmas and paleas thresh-free from the ripe grain. In others such as oats and barley, the lemma and paleas are tightly wrapped round the kernel of the grain and the entire structure is shed as a unit.

In barley the lemma and palea are fused to the grain and only loosely attached above the germ area. In these species, the morphological characters of the grain are defined by the surface features of the lemma and palea. These characters are best observed on the ripe grain. In barley, the lemma nerves may have pigment absent or present and if present then the degree of expression may vary. The nerves at the top of the lemma just before it extends into the awn can show varying degrees of spiculation and the base of the lemma can vary in shape. On the ventral surface of the grain, the palea view, lying in the furrow is a minute extension of the rachis called the rachilla, which has either short woolly hairs or long silky hairs and along the margins of the furrow some varieties have minute spiny hairs. Rachilla hair type and the presence or absence of ventral furrow hairs are two discrete state characters that are inherited independently of the environment and can be used to classify barley varieties into groups. Within these groups, other characters such as degree of pigmentation in the lemma nerves, which shows a continuous range of expression and is affected by the environment, can be used.

Most international protocols used to harmonize cereals variety descriptions use only a shortened list of characters. For specialist purposes, the number of characters used to describe some plant structures can be extended, e.g., barley rachilla characters:

- top level: rachilla hair type – short or long;
- additional characters: length of rachilla – very short to very long; and
- length of hairs at tip of rachilla – extending to tip of rachilla only to extend well beyond tip of rachilla.

These additional characters can be used to clinch the identification of some malting barley at the point of sale or intake for processing and can have considerable commercial value in negotiating commodity price.

Other characters of the barley grain include the shape of the lodicules, the two vestigial structures lying beneath the lemma next to the embryo, and the color of the aleurone layer. The latter is an important feature in malting and distilling. Some processors prefer varieties with a "white" aleurone layer for some malt products whereas others will accept varieties with a colored or "blue" aleurone. The color is caused by the presence of pigmented organelles in the cells of the aleurone layer – the layer of cells just beneath the surface of the kernel of the grain. Five genes control aleurone expression and the strength of pigmentation depends on the dosage, or number, of these genes present.

The morphology of wheat grains is more difficult. Without the attached lemmas and paleas, grain characters depend upon color of the grain (either red or white and the vast majority are red-grained), shape of the germ area and embryo, and length of the brush hairs. Other characters include a physiological reaction that develops when grains are immersed in 1% phenol solution. Image analysis techniques have been tried on wheat varieties but grain shape is affected by seasonal growth factors and variation within varieties can be greater than variation between varieties.

Oats are even more difficult to discriminate using grain characters even though the lemmas and paleas remain attached. Oats have a limited and more specialized market share and the few varieties that are bred tend to use parent varieties that are interrelated. All varieties have either a white or yellow colored lemma and the only other characteristics of use in identification are the presence or absence and length of hairs on the rachilla at the base of the grain. A small number of newer varieties thresh-free from the lemmas and paleas and here varieties are described and identified by the characters of the plants such as height, date to ear emergence, and glaucosity characteristics.

The Future

The General Agreement on Tariffs and Trade (GATT) that established the World Trade Organisation in 1995 contains important provisions covering the protection of intellectual property in the agreement on Trade Related Aspects of Intellectual Property Rights (TRIPS). The TRIPS agreement requires that members of the WTO who have ratified the GATT treaty have compatible legal systems in place that grant protection of plant varieties either by patents or a *sui generuis* system, or a combination of these methods. For most member countries, this means membership of UPOV and a PBR system based upon plant morphology. In Europe this has become a legal requirement as part of European Union Directives. Studies in plant and seed morphology are set to remain important in the foreseeable future. Plant breeders will still use morphological characters to purify candidate varieties before submitting them for tests and trials, and seed traders will still use morphological characters to verify variety at the point of sale.

However, the science of systematics is being revolutionized by molecular technologies. New species are being revealed and new ancestral relationships are being identified. Early work using biochemical and molecular markers for variety registration studies used nonfunctional markers. However, recent work has identified functional markers from parts of the genome that are known to be expressed. This has linked with studies to identify performance traits such as resistance to barley yellow mosaic virus and malting quality in barley and bread making in wheat. At the UPOV convention in 1991, the concept of dependent or essentially derived varieties was incorporated. An essentially derived variety is one that derives from an initial variety and that retains the essential characteristics of the initial variety but is clearly distinguished from the initial variety. It was accepted that the breeders of the initial variety could claim ownership or part-ownership of the essentially derived variety. "Genetic engineering" techniques may in future reduce the difference or "distance" between varieties and, if so, molecular techniques will be used to assess any claims of essential derivation.

This may enable tests and trials to move away from field sown plots to evaluations in the laboratory that will be independent of the local environment. It will enable beneficial traits to be recognized and transferred into new varieties and offers a new way of managing genetic resources that the studies of morphology cannot achieve. Molecular techniques may

also have the power to accelerate the production of new varieties into commerce by identifying performance trails and offer a way of managing variety registration methods much more efficiently and within legal requirements and boundaries. For the time being the future belongs to morphological and molecular techniques running in parallel.

GRAIN CROPS, OVERVIEW

R A Graybosch, USDA-ARS, University of Nebraska, Lincoln, NE, USA

Introduction

Plants considered "grain crops" are those producing small, hard dry seed or fruit consumed by man or his domesticated animals as a foodstuff, or processed for food or industrial purposes. "Grain crops" as a grouping, is, however, largely artificial. Plants producing useful grains have evolved in a number of plant families, and these families are not always closely related. Grains themselves are heterogeneous. Grains of cereal grasses represent an entire fruit (caryopsis), while those of other grain crops are the dry seeds of various types of fruits including legumes (pulses), achenes (sunflowers, buckwheats), siliques (canola), capsules (cotton), etc. Grains, therefore, are the result of convergent evolution, or the development of similar structures (grains) in diverse organisms. The actual genes involved in the formation of these structures might be different in each family of grain crops.

Grain crops of significance are listed in Table 1 according to their common English names and the equivalent botanical names (as Genus and species). When such lists are formulated, it is valuable to arrange species in a systematic fashion. This has been accomplished in Table 1 by showing taxonomic relationships, indicating those with close or distant relationships by grouping them in Orders, Families, and at times, Tribes. Taxonomy is the science of the identification, classification, and nomenclature of organisms. It is used to insure proper identification of organisms under study, to provide scientific accuracy to organisms in published works, to provide a universal system for the naming of organisms through use of scientific (Latin) names, and to define genetic and evolutionary relationships (or the lack thereof) between organisms via classification into groups of related species. Taxonomists have been

		Gossypium herbaceum L.	Arabian, Levant or Maltese cotton
		Gossypium hirsutum L.	American cotton, upland cotton

[a] From *Mansfeld's Encyclopedia of Agricultural and Horticultural Crops.*

engaged for several centuries in the naming and classification of all organisms populating our globe. Taxonomy, therefore, allows grain scientists knowledge of which grain crops are closely related (in genetic and evolutionary senses) and which are not.

Grouping Grain Crops into Hierarchical Categories

All plants are assigned to a specific species, or a group of closely related, morphologically similar individuals, capable of intermating, and reproductively isolated from members of other such species. Groups of closely related species are placed within a larger group known as a genus (pl. genera). Closely related genera are placed within families. Families sometimes are split into smaller groups known as tribes. In practice, however, the use of tribes tends to be applied only when discussing large (for example the grasses) families. Related families are grouped together in orders, related orders into classes, and related classes into divisions. Plant scientists tend to use the term "division" as the equivalent of the animal scientists' "phylum." Finally, divisions are grouped into kingdoms. All flowering plants belong to the Kingdom Plantae, Division Anthophyta. Division Anthophyta is divided into two classes, the Liliopsida (monocotyledonous plants) and the Magnoliopsida (dicotyledonous plants). Grain crops are found in both divisions, indicating their common ancestors diverged quite early in the evolution of flowering plants.

While plant species are the fundamental unit of taxonomy, they may themselves be divided into smaller units. Morphological variants of a species with a unique geographic or ecological distribution are termed "subspecies." Some taxonomists have used the term "variety" rather than "subspecies" but "variety" often has been applied indiscriminately for any morphological variant regardless of its

geographic or ecological distribution. The term "race" also is used, often to designate groups within subspecies or varieties. Unfortunately, there seems to be no unanimity on the use of these terms, and one taxonomist's "subspecies" might be another's "variety." The present treatment follows Mansfeld's Encyclopedia of Agricultural and Horticultural plants, and uses the term "subspecies." "Cultivar" designates a cultivated variety of a species or subspecies. Grain crop species might contain both cultivated and noncultivated subspecies, and typically numerous (as many as thousands) cultivars will exist.

Rules for Allocating Names

All plant species are assigned a scientific or Latin name that designates both the species itself, the genus to which it belongs, and the authority responsible for the naming of the species in question. For example, in the scientific name of cultivated barley, *Hordeum vulgare* L., *Hordeum* is the generic name, *vulgare* is the specific epithet, and L. stands for Linnaeus, the scientist responsible for first publishing the name of this particular species. Scientific names always are printed in italics, and always contain both the generic name, and the specific epithet. The specific epithet is never used alone. Within a published work, the generic name is used at the first mention of a species. Thereafter, the generic name may be abbreviated. Thus, *H. vulgare* may be used throughout the remainder of this article to designate barley, but *vulgare* may not be used alone. This "binomial system of nomenclature" traces its origin to the Swedish botanist Carolus Linnaeus, who employed it in his work *Species plantarum*, published in 1753. *Species plantarum* is viewed by botanists as the starting point of plant nomenclature and classification.

Linnaeus was so well known, and named so many species, that scientific names he coined carry only the abbreviation "L." to designate him as the authority. In most cases, the entire family name of the authority is given, although abbreviations are used for a few well-known authorities. Various permutations on the authority name will be encountered. For example, the authority Host applied the scientific name *Triticum compactum* to club wheats, a morphologically distinct type of wheat grown for use in pastry and other low-protein flours. However, the authority Mackey decided that *T. compactum* was really not a distinct species from common or bread wheat, *T. aestivum* L., but was rather, merely a subspecies. Thus, the scientific name for club wheat became *T. aestivum* L. subsp. *compactum* (Host) Mackey indicating that while Host named the species, Mackey believed the assignment of specific rank to be unjustified. At times, an authority might prepare a voucher specimen and a name for a species, but fail to publish it. If a second authority later agrees, and publishes the name, both names appear, separated by the term "ex." If such a case occurred with Host and Mackey, the authority would be written Host ex Mackey. Other arrangements exist and are described in many of the references listed below.

Common Versus Scientific Names

Common names are the local, regional, or national names for plants. With the multitude of spoken languages in existence, common names for many crop species often are numerous. In scientific literature, common names for plants should be used only when the scientific name is presented at first mention of a plant species. Use of common rather than scientific names can lead to needless confusion. Some plant species are known, even within a single language, by a multitude of common names. For example, the grain crop proso millet (*Panicum miliaceum* L.) is also known by the English common names common millet, French millet, hog millet, broomcorn, and broomcorn millet. Also, some common names have been applied to totally different species. In the Americas, "corn" refers to *Zea mays* L., while in Europe the term has been applied to barley (*H. vulgare* L.) or to spelt wheat [*T. aestivum* L. subsp. *spelta* (L.) Thell.]. The use of the scientific name would avoid the obvious confusion that might result from use of common names.

The Species Concept and Grain Crops

Species have been defined as groups of morphologically similar individuals sharing a common ancestor, capable of interbreeding, and reproductively isolated from all other such groups. While such a definition might appear concise, concrete, and easily applied, in practice, boundaries between species are not always clear. In addition, many plant species named over the course of taxonomic history have been found to be undeserving of this rank. Early taxonomists relied primarily on morphological features as a means of recognizing species. To some authors, any difference in plant appearance or morphology was justification for a new species assignment. Thus, some experts recognized more than 30 species of cultivated grain sorghum, while modern taxonomic treatments designate but one, *Sorghum bicolor* (L.) Moench. Exercise of natural selection by man on grain crops has led to the preservation of a plethora of morphologically distinct forms. However, genetic studies have shown that many of these unique morphologies are due to the presence of only one or a few genes. Hybridization studies also have shown that many morphologically

distinct forms can freely interbreed. For example, club wheat differ from common or bread wheat by having a more compact, triangular shaped inflorescence. To a morphologically based taxonomist, club wheat would appear to be a distinct species. However, genetic studies established that the compressed spike morphology was conditioned by a single genetic locus, and club wheat will freely hybridize with bread and spelt wheat. Thus, recognition as a distinct species was not warranted.

Reproductive isolation from other closely related groups is key to most species concepts. However, many grain crop species can successfully be mated with related species, and set viable seed. Often the F1 generation of such matings will be sterile, but, in some cases, limited female fertility will occur, and second generation progeny can be obtained via backcrossing. In addition, geneticists and breeders have developed sophisticated techniques such as embryo rescue and doubled-haploidy that allow gene transfer between even more distantly related species. To avoid confusion and taxonomic "lumping" it is best to consider two species distinct if, under normal circumstances (i.e., without the intervention of man) they will not produce viable offspring.

Early, morphologically based taxonomic treatments resulted in numerous scientific names being published for various forms of grain crop species. Later treatments, based more on genetic principles and evolutionary relationships, led to numerous changes in grain crop nomenclature. As scientists in the twentieth century became more aware of the work of scientists from other nations, numerous names were found published for the same species. Thus, numerous synonyms exist for most of our grain crops, and will be encountered in the literature. In such cases, the earliest published name takes precedence, and references such as Mansfeld's Encyclopedia of Agricultural and Horticultural Crops and others provide extensive lists of synonyms and accepted names.

Due to extensive morphological variation, numerous subspecific names have been assigned to grain crops and their relatives. Subspecies names are useful as a means of differentiating various forms of cultivated crops, especially when distinct market classes exist for each type. For example, common or bread wheat is classified as *T. aestivum* subsp. *aestivum*. Two morphologically distinct forms of *T. aestivum*, club wheat (*T. aestivum* subsp. *compactum*) and spelt (*T. aestivum* subsp. *spelta*) are grown and marketed for different end-uses. Use of the subspecies names, in such cases, is useful as it differentiates the various cultivated forms. Subspecies names also are useful to differentiate cultivated forms of plant species from wild ones. For example, durum wheat (*T. turgidum* subsp. *durum*) has several wild, semiwild, and formerly cultivated relatives including *T. turgidum* subsp. *dicoccoides*, *T. turgidum* subsp. *dicoccum*, and others. In both examples, use of the subspecies names serves to differentiate the morphologically different forms, while retaining an indication of the close genetic relationships between the various types. Such information is useful as an indication to geneticists and breeders as to the existence of close relatives of grain crops for use as gene donors in crop improvement programs. It also is useful as an indicator to people with dietary restrictions (e.g., those afflicted with celiac disease) of the true genetic relationship between grain crops.

The Major Families of Grain Crops

Plants classified as grain crops are found in both classes of the Division Anthophyta (Table 1), and include representatives of ten orders and eleven families. The families with the largest number of members are the Poaceae (Gramineae), also known as the grass or cereal family, and the Fabaceae (Leguminosae), the legume or bean family. These two families contain over ~70% of the species considered grain crops. Five species alone, including four grasses, wheat (*T. aestivum* and *T. turgidum* subsp. *durum*), corn (*Z. mays*), rice (*Oryza sativa*), and barley (*H. vulgare*), and the legume soybean (*Glycine max*) also provide over 70% of the world's metric tonnage of food from annual plants.

The Grasses

The grass family (Poaceae) contains the largest and, in terms of annual production, most important grain crops, the cereals. The Poaceae is one of the largest plant families, commonly divided into subfamilies, each, in turn, containing one or more tribes. Cereal grains (Table 1) are found in the subfamilies Pooideae, Bambusoideae, Chloridoideae, and Panicoideae, with the Pooideae and Panicoideae containing the largest numbers of grain crop species. Early systems of grass taxonomy relied heavily on morphological features, especially spikelet and inflorescence morphology. However, beginning in the 1950s, information regarding chromosome numbers, embryo structure, leaf anatomy, interspecific hybridizations, types of photosynthetic systems, etc. began to accumulate, and it became clear that the early arrangement of grass genera into subfamilies and tribes was largely artificial. In the 1960s, grass taxonomy was completely revised. Many earlier volumes still in wide use (e.g., Hitchcock and Chase's "Manual of the Grasses of the United States") reflect the original

groupings of grass genera. More recent references (e.g., Watson and Dallwitz's "Grass Genera of the World"), followed herein, should be consulted for proper tribal affiliation of grass genera.

The wheat and other members of the tribe Triticeae (subfamily Pooideae) are among the most important grain crops. Common or bread wheat, *T. aestivum* L. subsp. *aestivum*, and durum wheat, *T. turgidum* (L.) subsp. *durum* (Desf.) Husn., are the two most widely cultivated. Two additional subspecies of *T. aestivum*, *T. aestivum* L. subsp. *compactum* (Host) Mackey (club wheat), and *T. aestivum* L. subsp. *spelta* (L.) Thell. (spelt or farro), also are cultivated. Club wheat are used to produce pastry and other low protein flours, and spelt is grown largely as an heirloom crop, often in organic production systems. Some authors consider these to be separate species, but they both differ from typical bread wheat only in some aspects of spike morphology controlled by one or a few genes, and the forms will all freely hybridize, so recognition as separate species is unwarranted. *T. monococcum* L. subsp. *monococcum* (small spelt, einkorn, or faro) was once grown as a grain crop in most states bordering the Mediterranean Sea, and throughout Europe. *T. timopheevii* (Zhuk.) Zhuk. (Georgian or zanduri wheat) was cultivated in what is now the nation of Georgia. Both *T. monococcum* and *T. timopheevii* have all but disappeared from modern cultivation. Several additional subspecies of *T. turgidum* have been cultivated in historical times, but their importance either has diminished, or they are cultivated in local, isolated areas as relic crops. These include *T. turgidum* L. subsp. *abyssinicum* Vavilov (Ethiopean wheat), *T. turgidum* L. subsp. *carthlicum* (Nevski) A. & D. Love (Persian wheat), *T. turgidum* L. subsp. *dicoccum* (Schrank *ex* Schübler) Thell. (emmer), *T. turgidum* L. subsp. *polonicum* (L.) Thell. (Polish wheat), *T. turgidum* L. subsp. *turanicum* (Jakubc.) A. & D. Love (Khorasan wheat) and *T. turgidum* L. subsp. *turgidum* (cone, pollard or rivet wheat).

Other important members of the tribe Triticeae include barley (*H. vulgare* L.) and rye (*Secale cereale* L.). Triticale (X *Triticosecale* Wittm.) is a man-made crop, grown primarily as forage but also as a grain in some parts of the world. Triticales were developed via hybridizations between bread or durum wheats, and rye. Octoploid triticales contain all the genes of bread wheat and rye, while hexaploid triticales contain the genes of durum wheat and rye. *Secale* × *derzhavinii* Tzvelev, another man-made crop, has been developed as a perennial grain crop. Its cultivation is limited.

The oats, *Avena*, are more distantly related, being placed along with the wheats in the subfamily Pooideae, but in a different tribe, the Aveneae. Common oat, *Avena sativa* L., is the most commonly cultivated species. Its importance has diminished in historical times with the change from animal-driven to mechanized agriculture, but oats are still an important grain crop for human consumption, especially in the northern hemisphere. Other species of *Avena* have been grown as grain crops, but they either are no longer cultivated, or have been reduced to the status of relic crops. These included *A. abyssinica* Hochst. in Schimper (Abyssinian oat), *A. brevis* Roth (short oat), *A. nuda* L. (naked oat), and *A. strigosa* Schreb. (black or small oat). *Phalaris canariensis* L., the only cultivated member of the tribe Agrostideae, subfamily Pooideae, primarily is grown as a source of feed for caged birds.

Rice and its relatives Rice (*O. sativa* L., tribe Oryzeae) is the major food of nearly 50% of the world's population. Two forms or races of rice are recognized, "indica" types (race *indica*), grown in the tropics, and "japonica" types (races *japonica* and *javonica*), the temperate forms. These types are not recognized as subspecies. African rice (*O. glaberrima* Steud.) long has been cultivated in western and central Africa, but it has largely been replaced by *O. sativa*. *Zizania palustris* L., Northern wild-rice and *Z. aquatica* L. also members of the tribe Oryzeae, are cultivated and gathered from wild-populations in North America. *Oryza* and *Zizania* are the only grain crops assigned to the subfamily Bambusoideae. Indian rice-grass [*Oryzopsis hymenoides* (Roem. & Schult.) Ricker], formerly was gathered as a grain crop by Native Americans, and there have been some recent attempts to cultivate and market it. Indian rice-grass is so named for its superficial resemblance to rice, but it actually is placed in a different subfamily, the Stipoideae.

Maize, sorghum, and job's tears Maize (*Z. mays* L.) and sorghum [*S. bicolor* (L.) Moench.], are both members of the subfamily Panicoideae. Maize is placed within the tribe Maydeae, while sorghum belongs to the tribe Andropogoneae. Job's tears (*Coix lacryma-jobi* L.), rarely cultivated as a grain and ornamental crop, also is a member of the Maydeae. Many morphological types of both maize and sorghum exist, but, in both cases, only a single species and subspecies are recognized.

The millets and tef The millets are a taxonomically confusing group. The term "millet" evidently has been applied to any grass with a small round seed. Thus, the term is used to describe a number of, at times, only distantly related species. Most of the millets are placed in the subfamily Panicoideae, tribe Paniceae.

The most important millet in terms of annual production is pearl millet [*Pennisetum glaucum* (L.) R.Br.], most commonly grown in sub-Saharan Africa and in India. The remaining millets often are termed "minor millets." Of these, proso millet (*P. miliaceum* L.) is the most widespread, grown as a grain crop throughout Asia and into Eastern Europe. In North America it is largely grown as a feed for caged and domestic birds. Several additional millets are grown, primarily in Asia. The following also are members of the tribe Paniceae: *Setaria italica* (L.) P. Beauv. (foxtail millet), *Echinochloa esculenta* (A. Braun) H. Scholz (Japanese millet), and *E. frumentacea* Link. (sawa millet), *Paspalum scrobiculatum* L. (kodo millet), *Digitaria exilis* (Kipp.) Stapf (fonio or white fonio) and *D. iburrua* Stapf (black fonio), and *Brachiaria deflexa* (Schumach.) C.E. Hubb. ex Robbyns (Guinea millet). *Panicum sonorum* Beal (sowi millet) has seen limited cultivation in northern Mexico. *Eleusine coracana* (L.) Gaertn, known as finger millet or birdsfoot, actually is a member of the subfamily Chloridoideae, tribe Chlorideae, indicating that it is more closely related to tef than it is to the rest of the millets.

Tef [*Eragrostis tef* (Zuccagni) Trotter], subfamily Chloridoideae, tribe Eragrosteae, is cultivated as a grain crop in Ethiopia, and as a forage grass elsewhere. It is the only grain species in a fairly large genus of grasses.

The Legumes

The Fabaceae (legume or bean family) is second only to the Poaceae in terms of economic importance to man. This large family is divided into three subfamilies, the Papilionoideae, Caesalpinioideae, and Mimosoideae. Some authors treat these as separate families. All of the grain legumes are members of the Papilionoideae. Most grain legumes are members of the tribes Phaseoleae and Vicieae, although some also are assigned to the tribes Aeschynomeneae, Cicereae, Genisteae, or Indigofereae (Table 1).

Soybean, or soya (*G. max* L.) is the most important, in terms of annual metric tonnage of production. *G. soja* Siebold & Zucc., the wild progenitor of soybean, is a close relative, and the two are, at times, treated as one species. Intermediate types exist, likely the result of hybridizations between the two species. Intermediate types have been designated *G. gracilis* Skvortzov, but they now are recognized as representatives of the subspecies *G. max* subsp. *gracilis* (Skvortzov) Enken.

Edible dry beans are assigned to the species *Phaseolus vulgaris* L. A large number of morphological variants exist for this species, some being consumed as pulses, other for the edible pods. Common names include dry edible beans, kidney bean, navy bean, wax bean, green bean, field bean, etc. All are considered members of the same species. Other species of *Phaseolus* are cultivated, including the terpary bean, *P. acutifolius* A. Gray, *P. coccineus* L. (scarlet runner bean), and *P. lunatus* L. (butter bean or lima bean).

Arachis hypogaea L. (peanut) is widely cultivated in both Old and New Worlds. Two subspecies are grown, *A. hypogaea* L. subsp. *hypogaea* (Virginia peanut) and *A. hypogaea* L. subsp. *fastigiata* Waldr. (the Spanish or Valencia peanut). Other important grain legumes include *Vicea faba* L. (broadbean or fava) *Cajanus cajan* (L.) Millsp. (pigeonpea), *Cicer arietinum* L. (chickpea), *Lens culinaris* Medik. (lentil), and *Pisum sativum* L. (field or sweet pea). Several subspecies of *P. sativum* are cultivated, with *P. sativum* L. subsp. *sativum*, the common garden pea, being the predominant form. Other less common forms include *P. sativum* subsp. *abyssinicum* (A. Braun) Berger (A. Braun) Berger in Hedrick (Abyssinian pea) grown in Ethiopia and Yemen, *P. sativum* L. subsp. *asiaticum* Govor. (Asiatic pea), cultivated in Asia, and *P. sativum* L. subsp. *transcaucasicum* Govor., cultivated in the Caucacus mountain region.

Legumes of lesser importance include: *Cyamopsis tetragonoloba* (L.) Taub. (L.) Taub. in Engl. & Prantl (guar), cultivated at times as a grain but now more important as a source of guar gum. Other less common grain legumes are three species of the genus *Lupinus*, *L. luteus* L. (yellow lupin), *L. angustifolius* (blue lupin), and *L. albus* (white lupin). The lupins also are grown as ornamental plants. Widely cultivated, though of only local importance as grain crops are two species of the genus *Canavalia* (jack bean and sword bean), *Lablab purpureus* (L.) Sweet (Hyacinth bean), *Lathyrus sativus* L. (chickling pea), *Macrotyloma geocarpum* (Harms) Marachel & Baudet (Kersting's groundnut), *Psophocarpus tetragonolobus* (Stickm.) DC. (winged bean), *Vicia ervilia* (L.) Willd. (bittervetch), *Mucuna pruriens* (L.) DC. var. utilis (Wall. ex Wight) Baker ex Burck (velvet bean), and several species of the genus *Vigna*, *V. angularis* (Willd.) Ohwi & Ohashi (adzuki bean), *V. aconitifolia* (Jacq.) Maréchal (moth bean), *V. radiata* (L.) R. Wilczek (mung bean), *V. mungo* (L.) Hepper (black gram), *V. subterranea* (L.) Verdc. (Bambara groundnut), and *V. umbellata* (Thunb.) Ohwi & Ohashi (rice bean), and *V. unguiculata* (L.) Walp. (black-eye pea or cowpea).

Oil-Seed Crops and Pseudocereals

Several crops of various families produce grains from which edible or industrial oils are processed.

The mustard family (Cruciferae or Brassicaceae) contains several oil-seed species, most important of which is *Brassica napus* L. (rapeseed or canola). *B. nigra* (L.) Koch in Röhling (black mustard), and *B. juncea* (L.) Czern. (brown mustard) occasionally are cultivated for oil and to produce mustard. *Crambe abyssinica* Hochst. ex R.E. Fries (crambe) is another member of the mustard family used as a source of oil for various industrial purposes. One member of the family Pedaliaceae, *Sesamum indicum* L. (sesame) is cultivated as both a spice and as a source of sesame oil. *Ricinus communis* L. (castor bean), of the family Euphorbiaceae, is the source of castor oil, used in industrial applications. It is also infamous as the source of the toxin ricin, a seed protein. Linseed oil is derived from *Linum usitatissimum* L., a member of the Linaceae. *L. usitatissimum* also is the source of flax.

The Compositae (Asteraceae), or sunflower family, probably is the world's largest family, in terms of number of species. However, it contains only three members cultivated as grain crops, *Helianthus annuus* L. (sunflower), *Guizotia abyssinica* (L.f.) Cass. (Niger thistle), and *Carthamus tinctorius* L. (safflower). Sunflower and safflower primarily are grown as oil seed crops, but sunflower also is used as a grain for human and avian consumers. Niger thistle also is grown for birdseed.

Cotton species (Family Malvaceae, genus *Gossypium*) independently were domesticated both in the Old and New Worlds. *G. herbaceum* L. (Arabian or Egyptian cotton) was of Old World origin, while *G. hirsutum* L. (American upland cotton) and *G. barbadense* L. (American Pima cotton) and *G. arboreum* L. (tree cotton) were domesticated in the New World. Over 90% of the world's cotton production now is from *G. hirsutum* L. While primarily grown as a fiber crop, both oil and protein are processed from cotton seeds.

Pseudocereals are nonmembers of the grass family often milled to flour and used to produce flat breads and other products similar to those derived from true cereals. This is another artificial grouping, containing members of several plant families. Two members of the Chenopodiaceae are cultivated, *Chenopodium quinoa* Willd. (quinoa) and *C. pallidicaule* Aellen (canihua). The grain amaranths, *Amaranthus hypochondriacus* L., *A. caudatus* L., and *A. cruentus* L., are assigned to the Amaranthaceae. These five species all were components of the ancestral cultivated flora of Meso- and South America. Additional pseudocereals include *Fagopyrum esculentum* Moench. (buckwheat) and *F. tataricum* (L.) Gaertn. (Tartary buckwheat), both members of the Polygonaceae. Both probably were first cultivated in western China.

GRAINS OTHER THAN CEREALS, NONSTARCH POLYSACCHARIDES

L Ramsden, The University of Hong Kong, Hong Kong, People's Republic of China

Introduction

All plant tissues contain a large variety of polysaccharides many of which serve structural or reserve functions in the plant. However, the most important polysaccharide obtained from grain crops is starch and the focus in starch-producing grain crops is naturally on the yield of starch. The other polysaccharides present are granted seeming secondary importance as "nonstarch polysaccharides (NSPs)" a term, which covers a great variety of biological functions and chemical structures. There is a growing awareness that these polysaccharides can have considerable value both in human nutrition and for the food industry. In particular, noncereal grains show an interesting diversity of polysaccharides that are less familiar than the better studied NSP of the cereal grain. Noncereal grains include a great variety of potential species, many of which have not been analyzed for NSP content. Consequently, here it is only possible to present a limited selection together with some details of the structure and their value in products derived from grains.

Polysaccharides in a grain can serve two major biological functions. They can act as the energy reserve in the endosperm or cotyledons or they may be involved in forming the structure of the grain tissues. Other functions in which polysaccharides can play essential roles are in the regulation of water balance during dormancy and imbibition, and in the protection of the seed against predation and attack by pathogens. In cereals, only starch has amajor reserve function but in dicotyledonous grains other polysaccharides are found to act as reserves, often together with starch.

In common with all plant tissues, the tissues forming a grain are composed of cells, each of which is defined by a cell wall. The cell is the basic structural unit of plants and cellulose is the basic structural component of the plant cell wall. All higher plant cell walls contain not only cellulose but also a number of other polysaccharides that are important in maintaining the structural integrity of the cell wall and controlling cell wall permeability. Other components may be involved in interactions with neighboring cells and the environment.

The cell walls of plants display a composition which is characteristic of the taxonomic group in which the plant is found. In the angiosperms, there are consistent differences in the pattern of cell-wall polysaccharides present between dicots and

monocots. Thus, cereal plant cells possess cell walls typical of monocot grasses and this also applies to the endosperm cells in the cereal grain. The cell wall is formed from two types of wall, the primary and the secondary. Primary walls are those first laid down after a cell is formed and are thinner and more flexible than secondary cell walls which are found in mature cell types. Both primary and secondary cell walls contain cellulose but the cellulose fibrils of the primary cell wall are thinner and more loosely arranged; in the secondary cell wall the cellulose fibrils are closely packed into organized layers that are linked to each other by cross-links. Endosperm cells are typically larger and have thinner cell walls than other tissues in the plant, so the proportion of cellulose present can be lower than in other tissues.

Seed-bearing plants deposit energy-containing reserves to support growth of the embryo within the seed. While the major reserve polysaccharide is indisputably starch, there are a number of other polysaccharides, which are used particularly within the plant family of the leguminoseae. Starch reserves are stored in the cytoplasm in amyloplasts, but the nonstarch reserve polysaccharides in seeds are deposited in highly thickened walls of endosperm cells without a structural function.

Distribution of Grain NSPs

There is a clear distinction between monocot and dicot grain nonstarch polysaccharides, which reflects the differences between the monocot and dicot cell wall. The actual levels present in any grain sample can also vary depending on the growth conditions and particular genotype. The distribution of NSPs in dicot grains is more difficult to assess due to the variability in designation of what constitutes a dicot grain. In dicots, mixed linkage β-glucans (Figure 1) are absent and arabinoxylans, though they may be present in dicot cell walls, should generally be expected to be largely replaced by xyloglucan which is the main hemicellulose in dicots. Xyloglucans can also be found as a reserve polysaccharide in a number of seeds. Galactomannans are found as seed-reserve polysaccharides in several dicot families, though their commercial importance as food additives is derived from their presence in large tree seeds, they are also present in some smaller grains.

Uses of Grain NSPs

The presence of high levels of NSPs in grain products will reduce the nutritional value of the grain, a factor that is of significance in the animal feed industry. An important feature of NSPs is their ability to bind

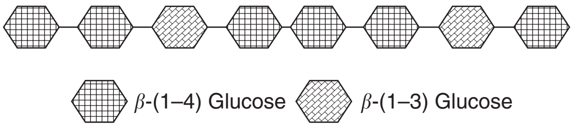

Figure 1 The sequence of glucose units in a mixed linkage of β-(1–3) and β-(1–4) glucan.

water, which allows them to act as hydrocolloids and disproportionately influence the rheology of aqueous systems. In baking, the NSPs of wheat can enhance water retention and texture of bread and cakes. Purified NSPs can be used as raw materials for the food-additive industry, which is a major user of polysaccharide texture modifiers, stabilizers, and gelling agents. Currently, traditional grains are not major sources of industrial polysaccharide hydrocolloids but high demand on traditional supplies makes this a competitive area for development. However, one of the major benefits of NSPs is that on consumption they contribute to the dietary fiber content of the food.

Dietary Fiber

The NSPs together form the major part of the dietary fiber of grain crops. Dietary fiber is the fraction of a consumed food which is not degraded in the gut. As human digestive enzymes can only cleave α-(1–4) glucan bonds, polysaccharides other than starch are part of the dietary fiber. Dietary fiber can be both soluble or insoluble. There are a smaller number of other polymers present in plant tissues, such as lignin, which also form part of the dietary fiber. However, the simplest available measure of the quantity of NSP in grains is the level of dietary fiber present (Table 1) and often this is the only figure available for many minor grain crops that have not been analyzed in detail for polysaccharide composition.

Although unable to contribute to human nutrition in terms of provision of energy, the dietary fiber is recognized to form an important component of our diet for the correct functioning of the digestive system. Polysaccharides through their high water-binding capacity play an important part in providing bulk to the gut contents to allow easy passage through the intestine. The human digestive system developed to cope with a diet rich in high fiber plant material with a large volume and is less well suited to the modern high fat, energy rich, low volume diets of industrialized countries. This deficiency in the modern diet can be overcome through the consumption of grain products high in dietary fiber. Polysaccharides can also bind to dietary lipids and reduce their uptake into the body, a factor which has been observed in the ability of high fiber diets to lower blood lipid levels

Table 1 Dietary fiber in cereal and legume grains

Cereals and grains	*Total fiber*
Wheat	14.6
Barley	22.6
Rice	2.4
Sorghum	10.1
Millet	8.5
Maize	13.4
Oats	9.6
Rye	14.6
Triticale	18.1

with potentially beneficial consequences for the incidence of cardiovascular disease.

Insoluble Cell-Wall Polysaccharides

The main structural component of any cell wall is cellulose, a β-(1–4) linked polymer of glucose (Figure 2). It is the world's most abundant polymer, closely followed by the related glucan starch, but with the key difference that cellulose cannot be degraded by human digestive enzymes and cannot therefore contribute directly to our nutrition. Cellulose chains are long flat linear ribbons of glucose units, the number of which can exceed 10 000 and with molecular weights of over 1 000 000. Because the β-(1–4) linkage between the glucose units holds the chain in a flat conformation, it is possible for cellulose chains to align next to each other and form numerous hydrogen bonds between the sugar hydroxyl groups. The chains can stack together to form larger microfibrils which make cellulose highly insoluble and tough, an ideal building material for plants. The quantity of cellulose that is found in whole grains can vary from species to species and is largely a consequence of the thickness of the husk and seedcoat, which tends to have stronger, thicker cell walls that contain more cellulose. The cells of seed endosperms have only thin cell walls and in a well-filled grain the proportion of cellulose

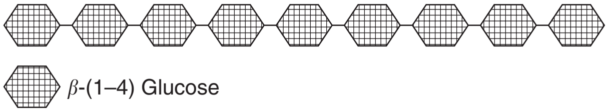

Figure 2 The sequence of sugar units in the β-(1–4) glucan cellulose.

to starch, or other reserve polysaccharide, should be low. Other largely insoluble polysaccharides such as glucomannans can occur in the walls of some plants, but quantities are typically low and although levels of up to 2% in some minor grain walls have been indicated, these would not have a major impact on grain properties.

Soluble Cell-Wall Polysaccharides

All plant cell walls contain a class of more soluble polysaccharides known as hemicelluloses which have a variety of different structures that serve various functions. These polymers contain a number of different sugar units and are classified according to their composition and solubility. The pattern of soluble polysaccharides present is characteristic of groups and species of plants. Purified hemicelluloses can show varying degrees of water solubility dependent on their size and structure, but all hemicelluloses are strongly bound to the intact cell wall, either by hydrogen bonding or by cross-linking to cellulose. The major function in the plant of hemicellulose is to increase the rigidity and impermeability of the cell wall.

The pectins are another class of highly soluble, cell wall related polysaccharides that are accumulated to high levels in some fruits but not to a great extent in most seed grains. Pectins are charged, acidic polysaccharides with a variety of structures based on rhamnogalacturonans, polymers of rhamnose and galacturonic acid with a number of other sugar substituents.

Dicot Arabinoxylans

Arabinoxylans can be found in many dicots but usually only at low levels. An exception is in linseeds, the seeds of the flax plant (*Linum usitatissimum*). Linseed is a traditional crop valued for the oil which can be expressed from the seeds. The seeds readily hydrate to form an arabinoxylan mucilage that can easily be extracted by incubation in cold water.

High levels of arabinoxylans are known to occur in seeds of various species of genus *Plantago* and one species, psyllium, has been used in commercial preparations of arabinoxylans. The arabinoxylan is present in the seedcoat and can be extracted with

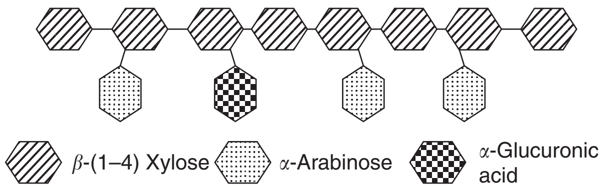

Figure 3 The arrangement of sugar units in arabinoxylan. α-Arabinose and α-glucuronic acid linked 1–2 or 1–3 to a backbone chain of β-(1–4) xylose units.

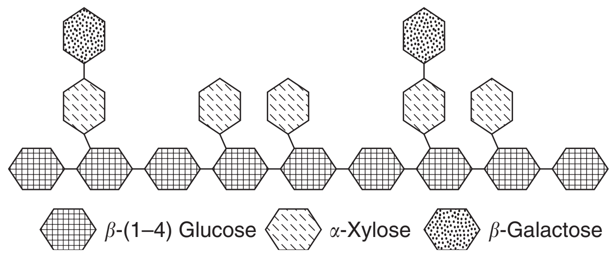

Figure 4 The arrangement of sugar units in xyloglucan. α-Xylose linked 1–6 to a backbone chain of β-(1–4) glucose units, some β-galactose linked 1–2 to the xylose units.

boiling water and yields are increased under mild alkaline conditions. The structure of the psyllium arabinoxylan is based on a xylan backbone substituted with arabinose and some uronic acids (Figure 3). Solubility in water is not high and the polysaccharide swells to give a weak gel. The gel shows a broad melting range ~80°C and is susceptible to syneresis on freeze/thawing but shows good stability over a range of ionic concentrations. Psyllium arabinoxylan is a soluble dietary fiber which is effective in lowering plasma cholesterol levels and which has traditionally been a component in laxatives where its high swelling power and mucilaginous gel eases the passage of gut contents.

Another abundant arabinoxylan is obtained from seeds of the quince tree (*Cydonia oblonga*). Seeds can be directly extracted with hot or cold water and a mucilage is readily released which is a mixture of cellulose microfibrils dispersed in a matrix formed principally of xylose and arabinose. The polysaccharide is easily soluble in cold water and produces a highly viscous mucilage but is not gel forming. Dispersions show good stability with respect to pH, salt concentration, and temperature. Quince seed arabinoxylan is mainly used for cosmetics applications in Middle Eastern countries, a number of food uses have been suggested, such as for use as a stabilizer in ice cream, but these have not been commercialized due to the high cost, poor availability, and variable quality of the gum.

Dicot Xyloglucans

The major hemicellulose of the dicot cell wall is a xyloglucan formed from a β-(1–4) linked chain of glucose units substituted with α-(1–6) xylose units. Galactose may be present linked β-(1–2) to some of the xylose units (Figure 4). Most legume grains contain a major proportion of xyloglucan in the cell wall as a structural hemicellulose. Less frequently high levels of xyloglucans are found in the seeds of some plants where they appear to have a reserve function such as in nasturtium (*Tropaeolum majus*) and the tamarind tree (*Tamarindus indica*).

Tamarind seeds can be ground to a hot-water-soluble flour to form a mucilaginous gel. The main polysaccharide is a xyloglucan with a β-(1–4) glucan backbone carrying 1–6 linked xylose and arabinose and galactose substituents in a ratio of ~1 : 2 : 3 for galactose : xylose : glucose. Small amounts of arabinose (and fucose) are found as alternate substituents to galactose on the xylose units. However, the proportion is low and would not be expected to exert a major influence on the properties of the polysaccharide. Tamarind xyloglucan can form a gel under acid conditions which remains stable at alkaline pH. Gels can also form in the presence of ethanol where cross-links arise due to the low solubility of some chain regions allowing aggregates to form. Tamarind gels are used in India for a range of traditional confectionery products. Xyloglucans are used as food additives in Japan for a wide range of products.

Reserve Polysaccharides

Seed-bearing plants deposit energy-containing reserves to support growth of the embryo within the seed. While the major seed reserve polysaccharide is starch, there are a number of other polysaccharides which are used as reserves, particularly within the legume family. Unlike starch, which is stored in amyloplasts, it can be inferred from the anatomy that in the cytoplasm the major nonstarch reserve polysaccharides in seeds are deposited in the cell wall but do not serve a structural function.

Apart from starch there is only one other major polysaccharide used by plants as a reserve outside the cell wall. These are polymers of fructose, the fructans which can have chain lengths of up to 250 sugar units, but are generally shorter and highly water soluble. Many grasses are known to use fructans for storage and for frost resistance. Potentially fructans may occur in the grains but there is little evidence for significant quantities and most sources of fructans are from tubers or stem tissue.

Galactomannans

Many seeds of the legume family contain high levels of reserve galactomannans. The seed galactomannans all possess the same basic structure of an α-(1–4) linked mannan backbone chain with varying degrees of substitution with α-(1–6) linked galactose residues (Figure 5). The ratio of galactose to mannose is roughly constant for a given species. The distribution of galactose along the mannan chain is not uniform but tends to be clustered in blocks of high substitution (rough regions) which are separated by intervening stretches with few galactose residues (smooth regions). Note that the arrangement of galactose substituents on the mannan backbone is neither regular nor uniform and clustering can occur with the effect stated but this is not intended to imply a block co-polymer structure as is observed for some other polysaccharides.

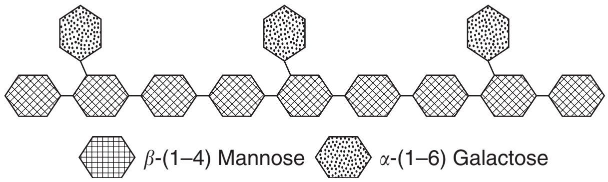

Figure 5 The arrangement of sugars in galactomannan. α-Galactose linked 1–6 to backbone chain of β-(1–4) mannose units.

Purified galactomannans for industrial usage are obtained from four main plant sources in the subfamily Ceasalpinioideae which are well characterized. There is Guar gum from the seeds of *Cyamopsis tetragonoloba*, Locust bean gum from seeds of *Ceratonia siliqua* (Carob tree), Tara gum from seeds of *Cesalpinia spinosa,* and Cassia gum from seeds of *Cassia obtusifolia*. Extraction of galactomannans involves de-hulling of seeds, crushing to remove the embryo, followed by milling of the endosperm to produce crude flour. The flour can be purified by dissolving in hot water followed by filtration and precipitation with isopropanol to remove impurities. The properties of galactomannans from different sources varies depending on the structure of the galactomannan which is characteristic of the source species.

The use of Locust bean galactomannan (LBG) in the Mediterranean and the Middle East has been part of traditional food preparation for hundreds of years. LBG has a galactose to mannose ratio of 1 : 4 and molecular weights ~300 000. The cold-water solubility of LBG is low and dispersions need to be heated to 85°C to achieve good dissolution, concentrations of up to 5% w/v being possible. Low solubility is due to the tendency for the linear mannan chains to strongly hydrogen bond to each other in unsubstituted regions of the chain, limiting opportunities for interaction with water molecules.

Though LBG does not itself form gels it can be used together with other hydrocolloids to provide gel formation. This synergestic gel formation can be observed with other nongelling polysaccharides such as xanthan gum. This property is attributed to the ability of the nonsubstituted regions of the linear mannan backbone being able to hydrogen bond to helical regions of the other hydrocolloids and provide cross-linking. LBG is widely used as a thickener and stabilizer in many foods such as ice cream, cheese spreads, salad creams, processed meat products, and pie fillings. A major use of LBG, and Guar, is in ice cream where it can act as an effective stabilizer to prevent ice crystal growth at low temperatures by restricting accretion of liquid water to existing ice crystals. The presence of large ice-crystals leads to a significant deterioration in ice-cream texture.

Guar galactomannan has long been used as a food ingredient in India. Guar is a linear β-(1–4) mannan with a higher proportion of galactose substituents than LBG, having a glactose:mannose ratio of 1 : 2 and this is reflected in the easier dispersion of Guar when compared with LBG. Guar can be dissolved at lower temperatures (20°C) than LBG as the extent of unsubstituted regions of mannan chain is smaller, reducing opportunities for interchain hydrogen bonding that would lead to aggregate formation and prevent hydration. The rheology of Guar is similar to that of LBG – pseudoplastic and decreasing with temperature, with good pH stability. Gel formation is again only observed when other polysaccharides are added, but the ability of Guar to participate in such synergistic actions is weaker than that of LBG, and this is also attributed to the reduced extent of galactose free regions of the mannan chain, which could form close hydrogen bonding with another polysaccharide.

Galactomannan from Tara seeds has a galactose mannose ratio of 1 : 3, intermediate between those of LBG and Guar. The rheological properties are similar to those of LBG. Cassia galactomannan has an average galactose/mannose ratio of 1 : 5 and can only be solubilized after boiling when a high viscosity solution can be obtained. The structure of the gum is rather variable and fractions of different solubility are obtained due to varying degrees of galactose substitution.

Like the above tree seeds of the legume subfamily Ceasalpinioideae the major grain legumes in the subfamily Papilionoideae can also contain galactomannans. Fenugreek is a legume from the Mediterranean region, which contains high levels of a seed

endosperm galactomannan with a galactose mannose ratio approaching 1 : 1. Fenugreek galactomannan is cold-water soluble, forming solutions with a lower viscosity than the other galactomannans. It has potential to act as an emulsifier and can show a good ability to stabilize oil/water interfaces. Soybeans contain a potentially useful seed galactomannan with a galactose/mannose ratio approaching 1 : 2. Lupin seeds are unusual in containing a reserve polysaccharide which is structurally unrelated to other legume reserve galactomannans, this is a galactan (or arabinogalactan) with a main chain of β-(1–4) linked galactose and low levels of arabinose substitution.

Identifying NSPs

As new species are tested for potential as grain crop production, investigation of the presence of any NSPs should be an essential component in the study. It is relatively simple to ascertain the presence of any unusual polysaccharides where these contain different sugar units from those in the known polymers. Analysis of the monosaccharide composition of a grain sample after total acid hydrolysis will often be sufficient to infer the presence of polysaccharides from the ratios and quantities of monosaccharides present. Monosaccharide analysis can be conducted directly by high-performance liquid chromatography or by gas chromatography after generation of volatile sugar derivatives. Where the polysaccharides differ more subtly by variation in the linkages between the monosaccharide units, then the method of choice is usually methylation analysis, requiring the production of methylated sugar derivatives reflecting the positions of glycosidic linkages which can then be analyzed by GC/MS. Where soluble polysaccharides are under investigation, clear signals reflecting the position of glycosidic linkages can sometimes be obtained relatively rapidly by NMR analysis in solution.

The above analytical techniques will usually be complemented by prior separation of polysaccharides present into different fractions depending on their solubility in solvents of different ionic strength and pH. Using the water solubility/insolubility of a polysaccharide is a rapid way, which can simultaneously extract polysaccharides from a sample and distinguish among those present in the grain.

Conclusion

There exists an enormous diversity of NSPs which are potentially present in seeds. The polysaccharides of the major cereal crop grains are now well known but as the exploitation of grain resources expands to include new and often diverse dicot plant resources new nonstarch polysaccharides will be encountered. Many of these new grains have not been fully investigated for the composition of minor polysaccharides present in the endosperm, which may have a significant impact on the properties of grain-derived products. Similarly there are considerable opportunities for the development of new grain crops to exploit NSP resources that are presently obtained from related species with much lower yields. Eventually we may see nonstarch polysaccharides no longer being regarded as a nuisance by reducing the value of a grain, but instead representing the major economic product.

GRAIN PRODUCTION AND CONSUMPTION

Contents

Overview

T Beta, University of Manitoba, Winnipeg, MB, Canada

Introduction

The term grain is used to include cereals (wheat, rice, and the coarse grains such as maize, barley, sorghum, oats, and rye), oilseeds, and pulses. Wheat, rice, and maize are the leading grains in terms of global production and area planted. Production of oilseeds and pulses has been driven by the world demand for high protein, vegetable oil, and animal feeds. World grain production has fallen short of consumption since 2000. The annual deficits for 2000–02 have caused a precipitous drop in grain stocks, reaching the lowest level in 30 years. The carryover stocks for wheat, rice, and maize at the end of the 2002 crop year amounted to 23%, 28%, and 15% of annual consumption respectively, the lowest in 28, 18, and 40 years, respectively.

The leading grain producers are the US, China, and India. Grains are produced in different geographical regions and either consumed in areas where they are produced or exported to countries where there is deficit in production. For example, the US produces maize for industrial processing but also exports to Japan for the meat industry. China produces most of the world rice but exports very little. Major grain exporters are the US, Canada, Australia, Argentina, and EU. Countries in NE Asia and North Africa import large quantities of grain. The grains are used for human food, livestock feed, and industrial processing other than food or feed.

World Grain Production of Cereals, Oilseeds, Pulses

World grain production, particularly in wheat and rice, increased substantially between 1961 and 1980 due to the increase in yields per ha or the "Green Revolution" (Figure 1). Since then, per capita (per person) grain production has not increased much as most of the easily realizable benefits of plant breeding, fertilizer, machinery, and irrigation have already been achieved. Production of grain per ha is close to the maximum obtainable through photosynthesis, hence, world grain production has not matched increases in the world's population. Low grain prices at planting time, high temperatures, and water shortages are the major factors contributing to reduced grain harvests. The fall in production has triggered an increase in the prices of wheat and maize and a corresponding increase in products (bread, breakfast cereals, pasta, and livestock products, including meat, milk, and eggs) derived from these grains.

World production of cereals (wheat, rice (paddy), and coarse grains) in 2002 was 572, 576, and 880 million tons (Mt), respectively (Table 1). Total cereal production is shown in Figure 2 as an average of 10 year periods beginning 1961. There was a 30% increase in cereal production during the period between 1971–80 and 1981–90. The rate of increase in cereal production has been slowing since the days of the Green Revolution in the 1970s. Table 1 shows world production of cereals, wheat, rice, maize, barley, sorghum, millet, and rye for the period 1992–2002. Data on yields and area harvested is also listed.

The world's wheat was produced in Asia (44%), Europe (37%), and North and Central (NC) America (12%) in 2002. About 91% of the world's rice was

produced in Asia. Africa and South America contributed ~3% each to the world's rice production. NC America, Asia, Europe, and South America contribute 43%, 27%, 13%, and 10%, respectively of the world's maize production. Wheat, rice, and maize contributed over 86% of global cereal production. World exports and imports of cereals by region in 2000 and 2001 are given in Figures 3 and 4, respectively. Pulses (including dry beans, dry peas, chick pea, and pigeon pea) were ~3% of total cereal production. Among oilseeds, soybean was ~9% of world cereal production.

Wheat

Wheat is produced under diverse climate conditions ranging from dry land with limited moisture (US, Australia, Former Soviet Union (FSU), West Asia, North Africa) to land that either has adequate moisture (Western Europe) or needs irrigation (FE

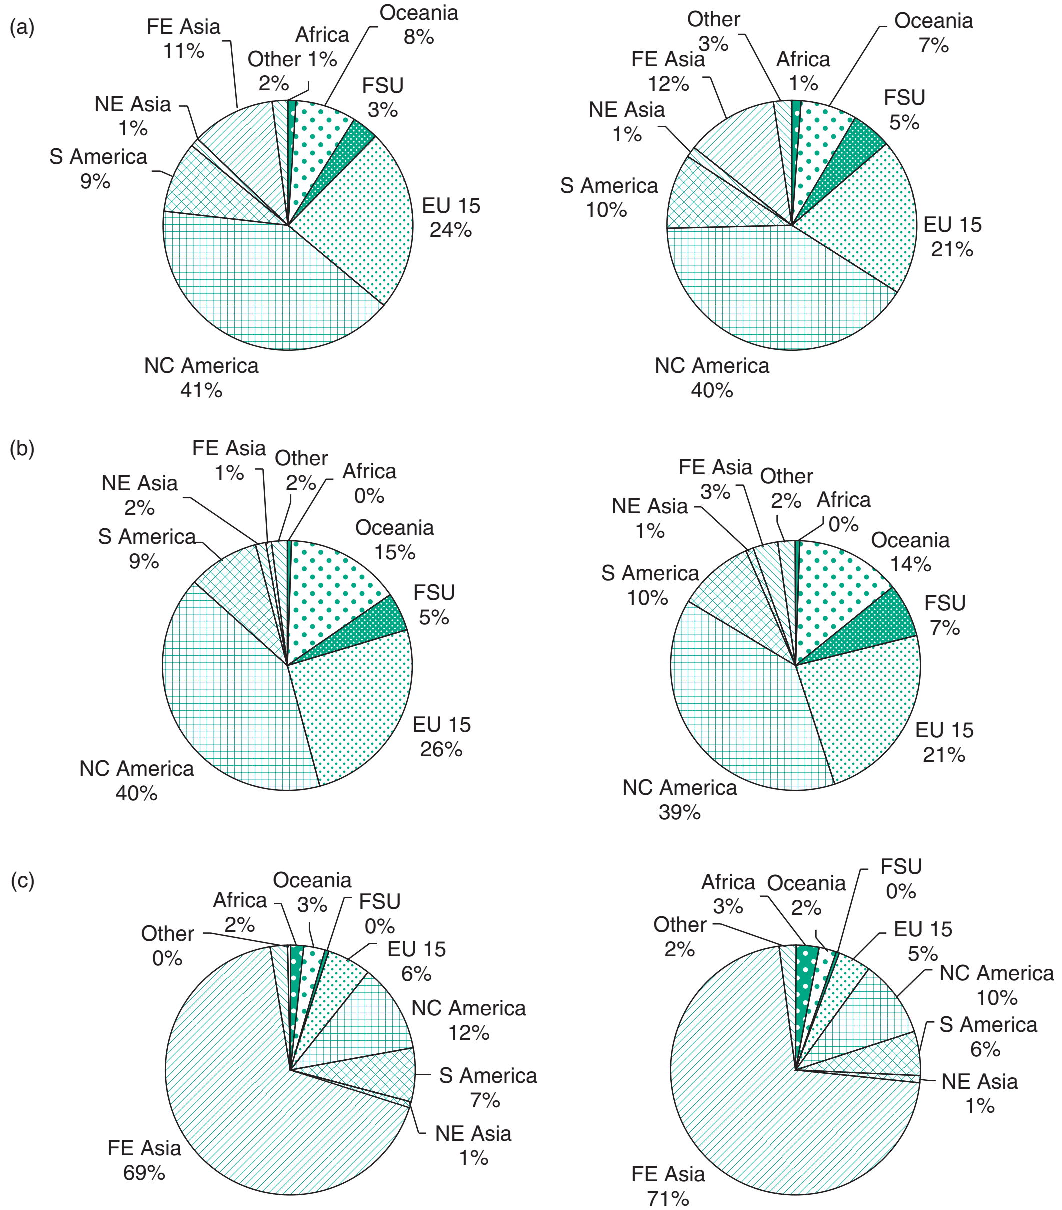

Figure 3 (a) World exports of cereals by region for 2000 (272 Mt) and 2001 (263 Mt); regional totals exclude processed secondary products. (c) World exports of milled rice by region for 2000 (23 Mt) and 2001 (26 Mt); regional totals exclude processed secondary products. (d) World exports of maize (corn) by region for 2000 (82 Mt) and 2001 (78 Mt); regional totals exclude processed secondary products. (Source FAOSTAT Database.)

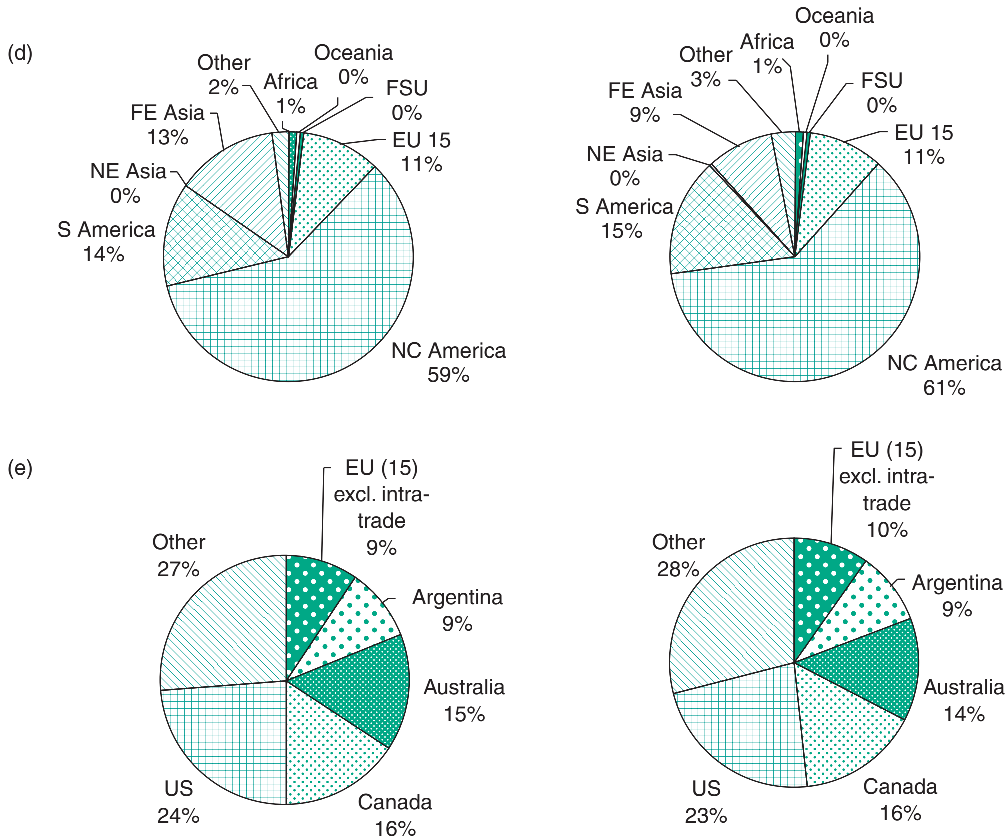

Figure 3 Continued.

Asia – China, India, Pakistan). Data on world wheat production, area harvested and yield for the period 2000–02 is given in Table 1. World wheat production decreased by 18 Mt in 2002 from the previous year (Table 1). The area harvested declined by 4 million ha (Mha) but yields remained unchanged. Yields are forecast to decline in 2003 due to insufficient rains in some areas in China and Canada, continued drought in New South Wales, Australia, and hot, dry weather in the Russian Federation, Ukraine, and many parts of Europe. The average global wheat production increased tremendously during the period 1960–80 largely due to an increase in yield. In developed countries, wheat yields tripled between 1950 and 1996 due to new wheat varieties and improved technologies including methods of sowing, irrigation, fertilizer application, moisture retention, and integrated pest management. Potential yields are still to be realized in African and Asian developing countries due to several constraints including inadequate water, infertile soils, poor weather, and lack of inputs. The major wheat producing countries by regions are China, India, Pakistan (FE Asia), Iran and Turkey (NE Asia), US and Canada (NC America), Argentina (South America), Australia (Oceania), Russian Federation, and Ukraine (FSU), and France, Germany, and UK (EU 15).

Bread wheat is planted on 93% of world wheat growing area while durum and soft wheat occupy the remainder. Spring types are sown on two-thirds of the land devoted to wheat in developing countries. Winter wheat is largely cultivated in Turkey, Iran, China, Europe, and US. The area planted in US is expected to increase by 6% due to strong wheat prices. Higher wheat production is expected in US due to support under the Farm Security and Rural Investment Act. EU wheat area is forecast to decline by 4% from 2002 due to low prices. The latter has been partly attributed to the near-record imports of wheat from Eastern Europe and the FSU.

The five major wheat exporters are Argentina (South America), Australia (Oceania), EU (15), Canada, and US (NC America) (Figure 3). The Russian Federation and Ukraine (FSU), both nontraditional exporters are expected to continue their wheat exports in 2003. India and Pakistan produce enough wheat to meet their country needs. Developing countries in Africa, Asia, South America accounted for ~60% of world wheat imports in 2000 and 2001 (Figure 4). Imports have risen over the

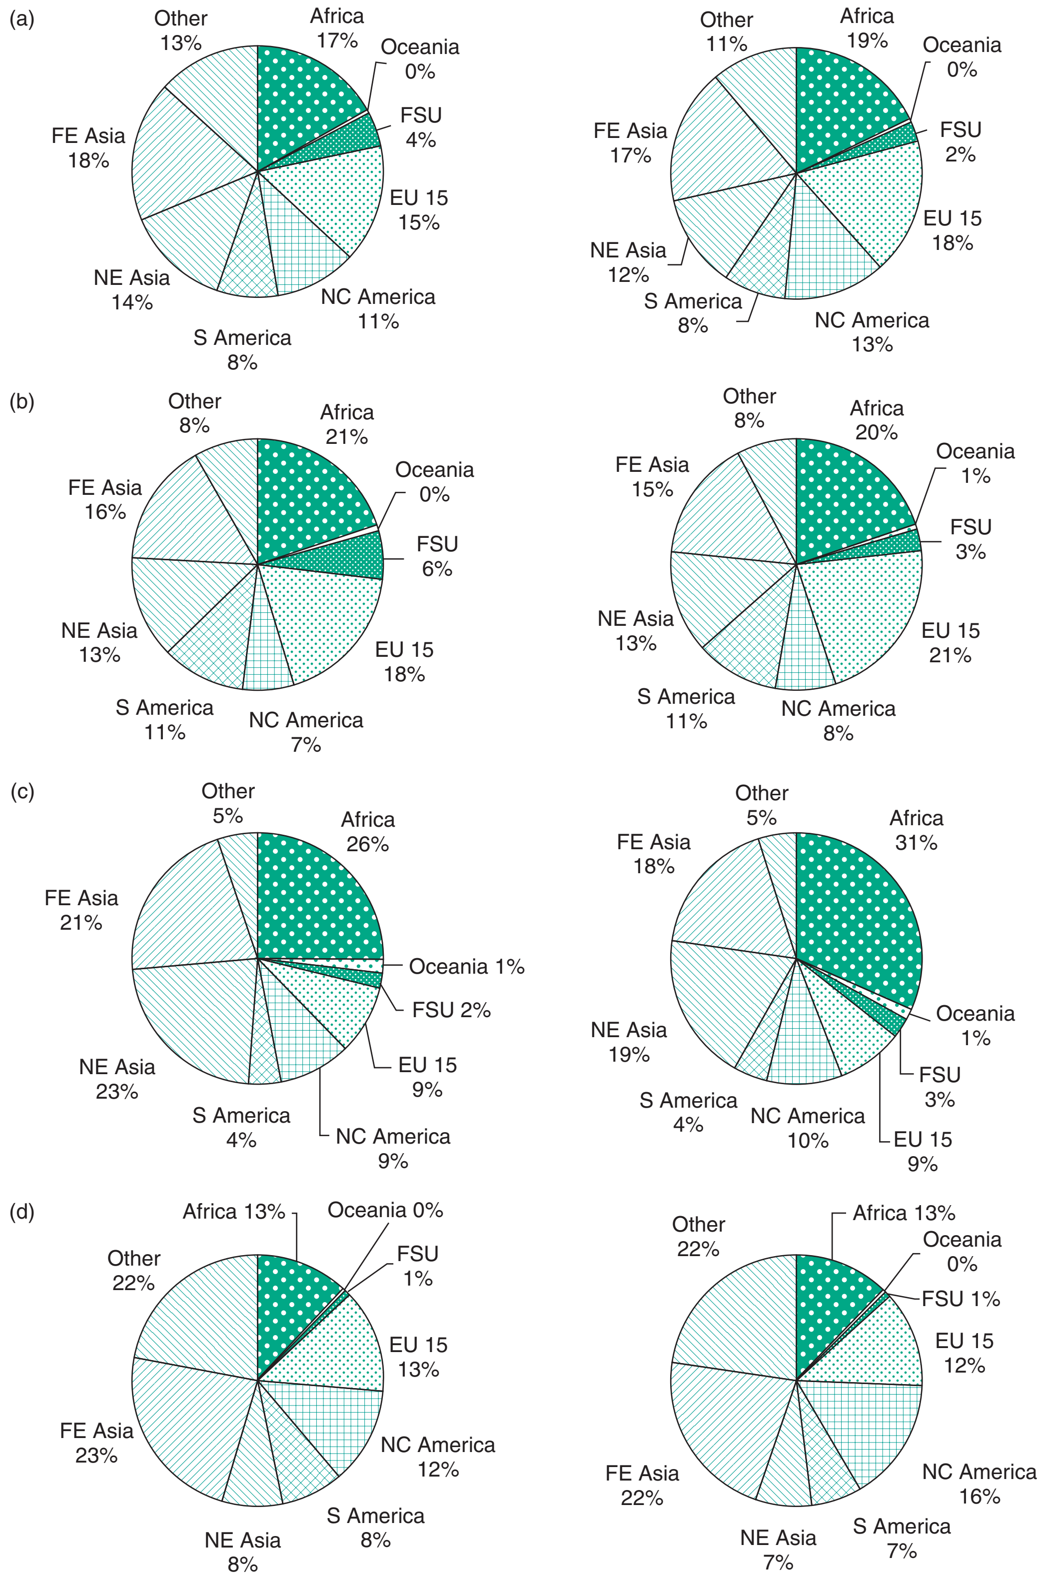

Figure 4 (a) World imports of cereals by region for 2000 (267 Mt) and 2001 (252 Mt); regional totals exclude processed secondary products. (b) World imports of wheat by region for 2000 (115 Mt) and 2001 (110 Mt); regional totals exclude processed secondary products. (c) World imports of milled rice by region for 2000 (22 Mt) and 2001 (23 Mt); regional totals exclude processed secondary products. (d) World imports of maize by region for 2000 (81 Mt) and 2001 (82 Mt); regional totals exclude processed secondary products. (Source FAOSTAT Database.)

years. Major wheat importers include North African countries (Algeria, Morocco, and Tunisia), FSU, West Asia, and the tropical belt. World wheat stocks are forecast at 133 Mt, reflecting smaller output from the EU, FSU, and Australia. Projected total carry-overs for the five majors are at 37 Mt, 3 Mt more than at the end of 2002. This is due to increase in US carryover stocks.

Figure 5 shows consumption of wheat in the EU, FSU, NC America, South America, NE Asia, FE Asia, and Africa in 2000. Most wheat is used for human consumption with a limited amount going into livestock feed. Projected world wheat consumption in 2003 is at 596 Mt with lower feed use in the EU and FSU. About 65–70% of world wheat flour is consumed as bread. The demand is higher for semolina than flour in some European countries. Wheat dry milling produces flour, semolina, bran, and germ. The primary products of milling are used largely in baking and extrusion to produce breads and pastas. Wheat germ oil and meal are valuable co-products. The bran, a by-product of milling, is used in high fiber foods and as an animal feed ingredient. Wheat is also used as a valuable feed ingredient for milk and beef livestock as it is more nutritious than maize, sorghum,

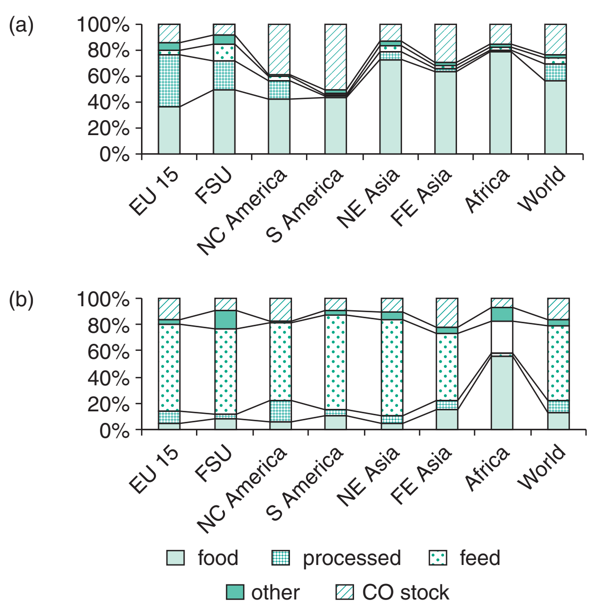

Figure 5 Wheat and coarse grain consumption and carryover (CO) stocks by regions for 2000 in Mt. (a) Total wheat consumption and CO stocks in selected regions were 91 and 15 (EU 15), 65 and 5 (FSU), 54 and 34 (NC America), 23 and 24 (South America), 46 and 7 (NE Asia), 224 and 93 (FE Asia), 43 and 8 (Africa), and 582 and 175 (world). (b) Total coarse grain consumption and CO stocks in selected regions were 98 and 19 (EU 15), 52 and 5 (FSU), 283 and 60 (NC America), 59 and 6 (South America), 29 and 3 (NE Asia), 229 and 63 (FE Asia), 86 and 7 (Africa), and 888 and 169 (world). (Source FAOSTAT Database.)

and barley. Whole grain wheat is fed to animals in developing countries only if it has been damaged (sprouted or shriveled).

Rice

World production of paddy rice (unmilled or rough rice) was 576 Mt in 2002, a decrease of 21 Mt from the previous year. The area harvested decreased from 151 to 147 Mha during the same period. World rice production doubled from 216 to 448 Mt during the period 1961–83. The increase in average rice production was ~15% between the 10 year periods 1981–90 and 1991–2000 compared to 30% for the periods 1971–80 and 1981–90 (Figure 2).

Most of the rice is grown in developing countries. In 2002, Asia was responsible for 91% of the world rice production, 51% of the total crop being produced by China and India. Only small amounts (less than 5%) of world rice produced are traded internationally. World exports of rice by region for 2000 and 2001 are given in Figure 3. The major rice exporters include Thailand, United States, Vietnam, China, Pakistan, and India. Australia produces small quantities of rice but has large surpluses for export due to its small population. China produces most of the rice for domestic consumption. Myanmar (formerly Burma) is an emerging exporter of rice. "Basmati" rice is a high-quality product grown in Pakistan and Northeast India for sale at four times the price of local rice. Primary and secondary products from rice milling find way into the export market. For example, Thailand exports broken rice while China, Indonesia, Malaysia, Sri Lanka, Thailand, and Vietnam export edible rice bran oil. Many countries in NC and South America, Europe, and Africa are net importers (Figure 4). Africa imports 80% of its rice requirements.

Rice is a staple food, providing ~56–70% of total calories consumed in Bangladesh, Cambodia, Indonesia, Lao Peoples Democratic Republic, Myanmar, Thailand, and Vietnam. It provides less than 10% in most African and Latin American countries with the exception of Guinea, Guyana, Surinam, Liberia, Madagascar, and Sierra Leone where 31–45% of total calories consumed come from rice. It is consumed mostly as white polished grain that has been obtained by milling. Parboiled rice is popular in parts of Asia and Africa, and to a limited extent, in some European and American countries. Parboiling paddy rice concentrates nutrients, enhances flavor, and corrects some defects of the harvested crop. Popped or flaked rice is used for production of breakfast cereals. In some European and North American countries, health-conscious consumers prefer brown

rice in which the bran has been retained after dehulling to remove the husk. Other products such as the Japanese rice wine or "sake" or Laos rice "toddy" and liquor are obtained after fermentation of rice. In the US, brewers' grits produced from rice milling are used as a raw material for beer production.

Coarse Grains

World production of coarse grains (including maize (corn), barley, sorghum, oats, rye, millet, triticale, buckwheat, and quinoa) was 880 Mt in 2002 compared to 918 Mt in 2001. Among the coarse grains, maize, barley, and sorghum are most important in terms of total cereal production. World production of maize, barley, and sorghum was 602, 132, and 54 Mt respectively in 2002 (Table 1). Production of other coarse grains was below 30 Mt each. Projected production of coarse grains in 2003 is at 924 Mt. Increase in production of maize and sorghum crops is expected in US due to favorable weather conditions. Spain also expects a good barley crop. However, hot weather and dry conditions stressed maize crops in Central and Eastern Europe and in China.

World trade in coarse grains totaled 107 Mt with US, Argentina, China, EU, Australia, and Canada exporting 55, 12, 9, 9, 4, and 3 Mt, respectively. FE Asia, NE Asia, NC America, and Africa imported 42, 15, 20, and 12 Mt, respectively. Countries that imported large quantities (in Mt) of coarse grain included Japan (20), South Korea (9), Saudi Arabia (6), Mexico (11), and Egypt (5). There is a slight reduction in barley imports as North Africa's needs are smaller than previously expected for 2003. Figure 5 shows consumption (total 888 Mt) and carryover stocks (total 169 Mt) of coarse grains in the EU, FSU, NC America, South America, NE Asia, FE Asia, and Africa in 2000. World consumption and carryover stocks of coarse grains other than maize and barley were only 145 and 21 Mt, respectively for the same year. Coarse grains find greater use as animal feed compared to wheat. Maize and barley have been in abundant supply replacing wheat in animal feed rations in the EU, FSU, and Australia. Projected world coarse grain carryover stocks are at 151 Mt for 2003.

Maize Maize is the third most widely grown cereal crop after wheat and rice, comprising ~22–25% of total cereal production in the world. Maize is the preferred crop in Africa and Latin America. In Asia, it occupies the third position after wheat and rice. World maize production fell by 12 Mt from 614 Mt in 2001 (Table 1). The area harvested in 2002 was 139 Mha, 70% of which is in developing countries. However, only 50% of world maize production is harvested in developing countries. Yields have remained relatively low in developing countries (2.5 tons ha^{-1}) compared to developed countries (7.9 tons ha^{-1}) due to environmental, technological, and socio-economic factors. Developed countries make use of adequate inputs and a well-mechanized system for maize production. In 1961, world maize production was ~205 Mt. The figure rose to ~615 Mt in 1998 and after this peak in world maize production, rising production costs and shortage of foreign exchange in many developing countries have led to diminished production, and consequently, maize trade. There was a 50% increase in average global maize production between the period 1961–70 and 1971–80 (Figure 2).

World exports and imports of maize by region for 2000 and 2001 are given in Figures 3 and 4, respectively. The main maize exporters are the US, Argentina, France, China, Hungary, Canada, South Africa, and Germany. The US accounts for over half of the world maize exports. China supplies grain to its neighboring countries. China still has high (but declining) grain stocks enabling it to compete effectively with US for Asian export markets. More than 0.5 Mt on average were imported by 28 countries (Russian Federation, United Kingdom, China, Egypt, Israel, Netherlands, Indonesia, Venezuela, Saudi Arabia, Portugal, Peru, Malaysia, Italy, Iran, Syria, Spain, Japan, Morocco, Mexico, Turkey, South Korea, Dominican Republic, Colombia, Chile, Brazil, Belgium, Luxembourg, and Algeria) each during the period 1999–2002. Industrialized countries imported 80% of their maize requirements. Japan and South Korea are the largest importers, each importing 16 and 9 Mt respectively, in 2000.

Maize consumption was 607 Mt in 2000. The primary product of maize milling is the meal used for feed and food purposes. At least 65% of world maize production is used to feed livestock and 19% is used for human food. Other uses include industrial processing and seed. Secondary and derived products are obtained through dry milling and wet milling processes. Products include tortillas, maize flours, chips, snacks, breakfast cereals, starch, thickeners, pastes, syrups, sweeteners, grits, maize oil, soft drinks, beer, and whisky. In US, domestic consumption of maize has been increasing due to increased supplies, continued strong livestock feed demand, lower wheat feeding, and increased use of maize in ethanol production.

Barley World barley production was 132 Mt in 2002, down by 12 Mt from 2001 (Table 1). The

area planted was 52 Mha in 2002. World barley production is expected to increase by 7% in 2003 due to increase in production in Canada and Australia. Both have increased area planted and are forecast to achieve higher yields as they recover from drought. In the EU and Australia, supply of barley is expected to increase. In 2000, the major producers by region included EU (Germany, Spain, and France >10 Mt each), FSU (Russian Federation 14), NC America (Canada 13, US 6), NE Asia (Turkey 7), and Oceania (Australia 6). The EU is a major exporter of barley. The Russian Federation and Ukraine have become competitors with the EU in export markets. Exports from the EU also face competition from Australia and Canada especially for supply of malting barley. NE Asia and FE Asia imported 8 and 3 Mt, respectively of the total 18 Mt traded in 2000. Saudi Arabia, China, Japan, and Iran were the major importers. World barley consumption totaled 135 Mt in 2000. Feed use accounted for 72% of barley consumption while food use remained low. The latter is likely to increase due to the promotion of the soluble and insoluble fiber in barley and the healthful benefits of whole grain diets. Domestic consumption in the EU is expected to increase due to reduced supplies of feed wheat. Carryover stocks for 2000 were ~20 Mt.

Sorghum Sorghum occupies the fifth position after rice, wheat, maize, and barley. Area under production was 42 Mha in 2002 compared to 44 Mha in 2001 (Table 1). Global yield and production were 1 tons ha^{-1} and 54 Mt, respectively in 2002. US, Nigeria, India, Mexico, Argentina, China, and Australia are the leading producers. Most sorghum is produced by small-scale and subsistence farmers in semitropical regions of Africa and Asia and by other farmers in US and Latin America. Africa produced 37% of the world total in 2002 on 23 Mha, more than half the world total area. India has the largest area harvested to sorghum, although, there has been a significant reduction from 16 Mha in 1989 to 9.5 Mha in 2002. Production decreased in China from a peak of 6 Mt in 1994 to 2 Mt in 2002 due to a decline in area harvested. Argentina and the US have the highest average yield in excess of 4 tons ha^{-1}. Area under production as well as sorghum utilization has been increasing in Brazil. World trade of sorghum was 8 Mt in 2000 with US supplying 6 Mt to the export market and Mexico and Japan importing 5 and 2 Mt, respectively. Mexico, the fourth most important producer of sorghum at 5 Mt in 2002 is also the largest importer. FSU and Venezuela are also main importers. Sorghum is also an important commercial and export crop for Australia and Argentina. The crop is utilized for feed (51%), food, and other uses (41%). The US, Mexico, Argentina, and Japan are principal feed users.

Millets World production of all millets was ~23 Mt in 2002 (Table 1), 35% of which was produced in Africa. West Africa (Nigeria, Niger, Burkina Faso, Chad, Mali, and Senegal) produces ~70% of the millet output in Africa. Asia and Africa account for ~94% of global output of millet. India, China, Nigeria, Russian Federation, and Niger are the leading producers of millet. Small-scale farmers produce almost all millet for household consumption and localized trade. Very little millet (~0.2–0.3 Mt or 1% of world millet production) is traded internationally. India, US, Argentina, and China are the major exporters of millet. The European community accounts for more than 50% of the global imports. Millet is primarily dry-milled to produce cracked grain, grits, meal, and flour from which a number of secondary and derived products are made.

Oats World oat production in 2002 was 25 Mt, down by 2 Mt from 2001 due to a decrease in crop yields (Table 1). The total area harvested was 13 Mha with an average yield of ~1.9 tons ha^{-1}. World oat production for 2000 by region, in Mt, was 6.9 (EU), 8.5 (FSU), 5.7 (NC America), 1.2 (Oceania), 0.7 (FE Asia), and 0.3 (NE Asia). The Russian Federation and Canada are the leading producers. US oat production continues to decline as area allocated to oats is drawn to soybeans and maize, both of which offer relatively strong returns. Oat production in Canada is forecast to increase sharply from 2002. EU oats face competition from Canadian oats, the latter being able to serve requirements for US and Canadian mills. Carryover stocks are projected to increase from a record low of 2002. Exports are expected to increase considerably in 2003 due to an increase in production and improved quality. Oats is used for both human food and animal feed. High levels of soluble fiber in oats have contributed to its promotion as a healthy food ingredient.

Rye, triticale, buckwheat, fonio, quinoa, canary seed, and tef World production of rye, triticale, buckwheat, fonio, quinoa, and canary seed was 21, 10, 2, 0.25, 0.05, and 0.20 Mt, respectively in 2002. These grains comprised only 2% of total cereal production. World production of rye fell by 2 Mt in 2002 due to a small decrease in yields (Table 1). The Russian Federation, Poland, and Germany are

Table 2 World pulse and oilseed production (Mt) for the period 2000–01

Year	*Total pulses*	*Dry beans*	*Dry peas*	*Chickpeas*	*Cow peas*	*Pigeon peas*	*Soybean*	*Rapeseed*
2000	54	16	10	7	3	3	161	39
2001	53	16	10	6	3	2	176	35
2002	55	18	9	7	3	3	179	33

Source: FAOSTAT Database.

the major producers of rye. World buckwheat production declined from 3 Mt in 2000 to 2 Mt in 2002 as area harvested and yields decreased slightly. Fonio production fell slightly in 2002 for the same reasons. World quinoa production has remained unchanged from 2000 to 2002. Canary seed was planted on a global area of 0.26 Mha in 2002. Canada contributed 74% of world canary production in 2002. About 90% of the seed is exported mostly to Mexico, Brazil, and Belgium. Canary seed is currently used almost exclusively as birdseed. Rye, triticale, buckwheat, fonio, and quinoa are used for human food mostly as ingredients in baked products. It is projected that the demand for these grains will grow as whole grains continue to be promoted as healthy foods. Feed use, industrial use, and exports are forecast to increase with increased supplies.

World tef production fluctuated between 1.2 and 2.0 Mt during the period 1992–97. Tef is a staple food crop of Ethiopia as well as an export crop. Small-scale production of tef has begun in the US, Canada, Australia, South Africa, and Kenya. Tef is exported to the Middle East, North America, and Europe and others mainly for Ethiopians who immigrated to these regions. Tef is utilized for food in the form of flour that is then used to make "injera" (pancake-like bread).

Pulses

Table 2 gives data on world pulse production for the period 2000–02. FE Asia contributed ~40% of world pulse production. Pulse production tripled in NC America and Africa and doubled in the EU since 1961. India and Brazil are the leading producers of dry beans. China, France, and Canada compete for the dry pea export market. Major chickpea producers are India, Pakistan, Turkey, and Canada. Canada is the global leader in the export of dry peas and chickpeas. Other chickpea exporters include Turkey, Mexico, and Australia. Spain, India, and Pakistan form the major import markets. North Americans consume more beans than any other pulse. Peas are used for both livestock feed and human food. The proportion for the latter use is higher in Asia and Latin America than in Europe.

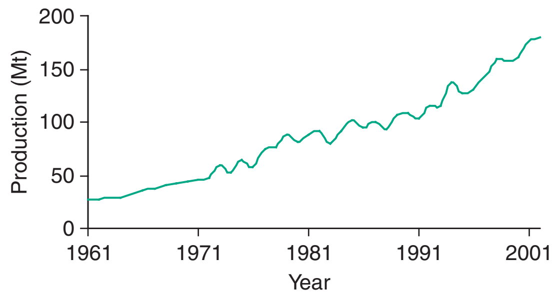

Figure 6 World soybean production for the period 1961–2002.

Oilseeds

World oilseed production was 194 Mt with soybean, cottonseed, rapeseed/canola, peanut, sunflower seed, palm kernel, and copra making up 60%, 10%, 10%, 9%, 7%, 2%, and 2%, respectively of the total production. World oilseed production has risen tremendously since the 1970s due to expansion of the area planted. Soybean, palm, rapeseed, and sunflower oil each accounted for 32%, 28%, 12%, and 9% respectively of the world vegetable oil consumption (93 Mt) in 2002. However, soybean made up 70% of the world protein meal consumption (187 Mt).

Soybean World soybean production was 179 Mt in 2002 (Table 2) compared to 26 Mt in 1961 (Figure 6). The US, Brazil, Argentina, and China accounted for ~39%, 26%, 18%, and 8% of total production in 2002. Production has been increasing since the 1950s due to increase in global area planted and yields. In Europe, production is limited due to poor climate and soil conditions. Production is now worldwide due to its ability to adapt to different types of soils and climates and versatile end uses. Brazil and Argentina continue to expand soybean-processing capacity as domestic policies continue to encourage value-added activities. World soybean exports were at 63 Mt in 2002. Major exporters were the US (44%), Brazil (33%), Argentina (14%), and Paraguay (4%).

Soybean is grown primarily for its meal in order to satisfy the feed protein requirement of broilers,

pork, and aquaculture producers, which are not met by meat and fish meals and meals from other oilseeds. Soybean oil is a secondary product. Derived products (made from soybean, soybean meal, or soybean by-product) include fermented foods (e.g., tofu, soymilk, and soy sprouts) and nonfermented foods (soy sauce, "miso," "tempeh," and "natto"). Soybean can be used to produce products differing in protein content. Other derived products include soy ice cream, yogurt, burgers, cheese, and meat analogs and salad oil, cooking and frying oils, shortening and margarines.

Rapeseed/canola Rapeseed/canola production was 33 Mt in 2002 compared to 26 Mt in 2001 (**Table 2**). About 90% was produced in FE Asia, EU, and NC America, that is 16.0, 9, and 4 Mt, respectively. China contributed one-third of total rapeseed production. Canada produced 84% of the crop in NC America. Canola is processed into vegetable oil for human consumption and meal for livestock feed.

Africa

J R N Taylor, University of Pretoria, Pretoria, South Africa

Introduction

Africa is the second largest continent with an area of 30.3 million square kilometers. It is the only continent that straddles both tropics. Hence, Africa has a predominantly subtropical and tropical climate. Most of northern Africa and much of southwestern Africa has a desert climate, with less than 250 mm of rainfall a year. The climate in the African tropics varies from warm and dry (rainfall 250–500 mm a year), through hot with a dry season (rainfall 500–1000 mm) to hot with rain all year (1000–3000 mm) towards the Equator. Only on the northwestern Mediterranean seaboard, the southern Cape and South African eastern seaboard is there a mild, warm, and wet climate (rainfall 500–1000 mm). Africa's natural vegetation mainly ranges from desert and semi-desert, though savanna, to sub-tropical and tropical broadleaf forest. One significant exception is the central part of South Africa, which is natural grassland, the "grassveld."

As of 2003, Africa's population is ~850 million (Figure 1). It has been growing very rapidly at ~3% a year, and has doubled since the mid-1970s. The population is still increasing rapidly but the rate

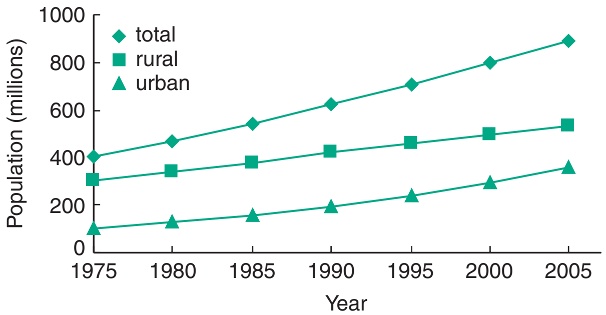

Figure 1 Africa's population.

of growth is slowing and is now ~2.5% per year. As can be seen, both the rural and urban populations are increasing, but urbanization is taking place much more rapidly. In fact, in some countries (e.g., South Africa and Zambia) well over 50% of the population now live in towns and cities. Obviously, Africa's high population growth rate, coupled with rapid urbanization is having a great impact on food security and food utilization.

This article examines the food situation in Africa with particular reference to the importance of grains as foodstuffs, grain agriculture, Africa's major grains and their production, grain consumption with respect to the types of grain foods and beverages in Africa, and the challenges and opportunities facing Africa regarding grain production and grain food processing. The data are from the Food and Agriculture Organization (FAO) of the United Nations.

Importance of Grains

Africa is an exception compared to the rest of the world in that quantitatively cereals are only the second largest foodstuff. Starchy roots are the largest, in particular cassava. The quantities are ~148 million tons (Mt) of cereals and 175 Mt of starchy roots (Table 1). However, it should be taken into account that, since cereal grains contain only ~12% moisture as against the ~23% for starchy roots, this translates to ~130 Mt dry weight of cereals and 40 Mt dry weight of starchy roots. With respect to cereals, Africa is also unusual in that only a relatively small proportion is used as animal feed, ~12.5%. Also of note is the fact that plant protein foods (pulses) at ~10 Mt are almost as important as meat (11.9 Mt). In fact, plant foods are far more important to Africa than animal foods, as seen by the fact that vegetable oils amount to ~9 Mt, whereas animal fats only 0.8 Mt.

Grain Agriculture

Whereas Africa produces essentially all its requirements for starchy roots, oil crops, and pulses, today nearly one-third of its cereal requirements have to be imported (Table 1). As can be seen from Figure 2, cereal production in Africa has been steadily increasing, from 66 Mt in 1977 to 117 Mt in 2001. However, as Figure 2 also shows, much of this increase has been due to the increasing land area under cultivation. There has only been a modest increase in yield, from 1.03 $t\,ha^{-1}$ in 1977 to 1.24 $t\,ha^{-1}$ in 2001. Increasing agricultural land has involved farming more marginal areas where the soil is poor and rainfall is intermittent, further exacerbating the situation. As a result, yields have generally remained low. Obviously, increasing cultivation area is unsustainable and it can be seen that there is evidence that the area of land being devoted to cereal cultivation is now increasing only slowly. This suggests that the practical limit of arable land area may be being reached.

Despite the increase in cereal production in Africa, it has not kept pace with the continent's population growth. In 1977, some 154 kg of cereals were produced per person. By 2001 this had fallen to 143 kg – hence the increasing quantity of cereals that has to be imported (Figure 2). Cereal imports increased from 16 Mt in 1977 to 46 Mt in 2001, an increase from 19% to 28% of the continent's cereals supply.

Table 1 Africa's domestic food supply (2001) ($t \times 10^3$)

Products	*Production*	*Imports*	*Stock changes*	*Exports*	*Total*

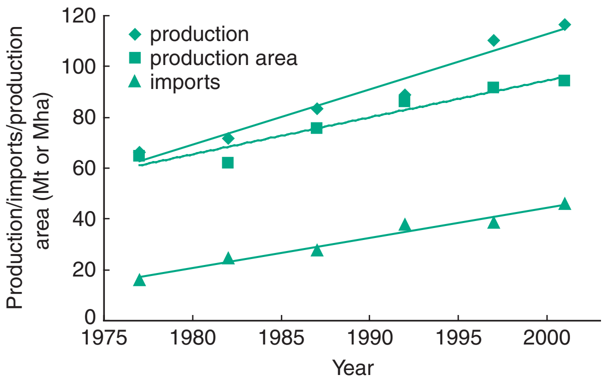

Figure 2 Cereal production and imports in Africa.

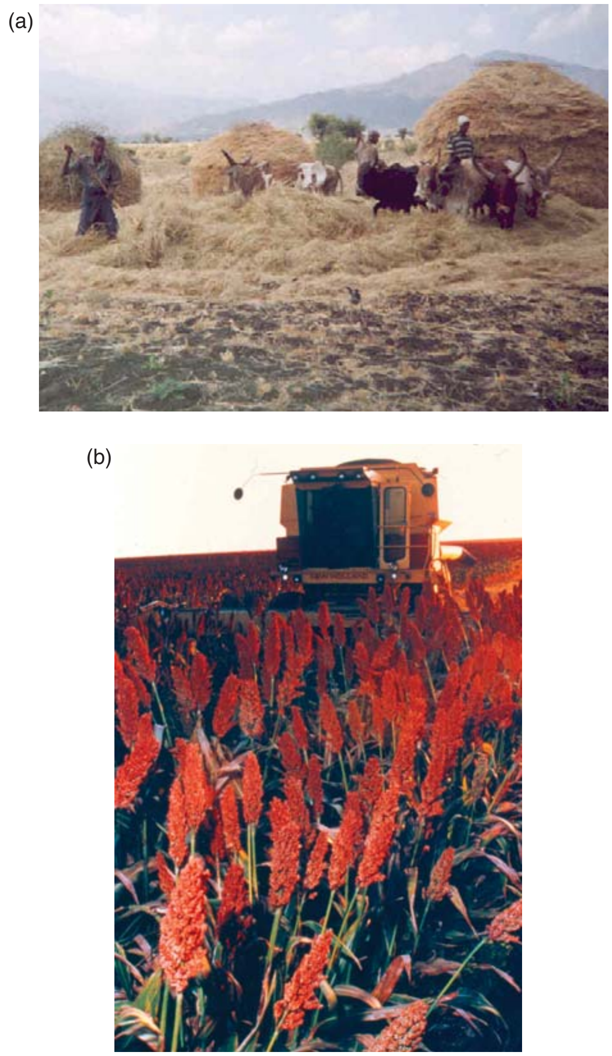

Figure 3 Cereal agriculture in Africa: (a) subsistence – harvesting teff in Ethiopia and (b) commercial – harvesting sorghum in South Africa.

The need to import an increasing proportion of cereal grains is related to the fact that much of Africa's agriculture is still subsistence farming. However, small-scale commercial and large-scale mechanized farming are widespread and well established. Unfortunately, the so-called Green Revolution has barely impacted on the subsistence and small-scale commercial farming sectors. Here, agriculture is characterized by traditional farming practices using manual labor and some draught animal power (Figure 3a), low inputs (no inorganic fertilizer or pesticides), and the use of low-yielding traditional varieties or landraces. Taking the example of sorghum, yields in Africa have remained more or less constant since the mid-1970s at less than $1\,\mathrm{t\,ha^{-1}}$. This compares to the sorghum yield of more than $3\,\mathrm{t\,ha^{-1}}$ in the USA. However, where mechanized, high-input agriculture using hybrid seeds on good soil exists in Africa, for example, in South Africa (Figure 3b), sorghum yields are much higher, $\sim 2.4\,\mathrm{t\,ha^{-1}}$.

Grains Produced

Cereal production in Africa is dominated by maize, which is a tropical (C4) cereal, at ~42 Mt (Table 2) (2002), some 37% of total cereals. As can be seen, production is very widespread across the continent both geographically and climatically. The top three producing countries are Nigeria, Egypt, and South Africa. In fact, maize production is recorded for 51 countries in Africa. The next most important cereals, in descending order, are sorghum, rice, and wheat, accounting for 17%, 15%, and 14% of total cereal production. Production of these three cereals is also widespread across Africa, with 42 producing countries being recorded for sorghum and rice, and 33 for wheat. However, there are some important differences with respect to their cultivation. Africa's production of sorghum, ~23 Mt is approximately one-third of world sorghum production. The area under cultivation in Africa, 23 Mha is almost half the world total. The major production is in the semi-arid tropics of northern Africa, from Nigeria and Burkina Faso in the west to Sudan and Ethiopia in the east. This is probably on account of the fact that sorghum, a tropical cereal, is indigenous to Africa and is very well adapted to harsh climatic conditions, being able to withstand periods of drought and water-logging. Sorghum requires a minimum of only 400 mm of water for cultivation, as opposed to the 500–600 mm needed by maize. In contrast, the production of rice, which is also a tropical cereal but requires much more water, is concentrated in areas of high water availability: the Nile valley of Egypt, tropical Nigeria, and Madagascar. Concerning wheat, which is a temperate (C3) cereal, its production is highest in countries in

Table 2 Grains produced in Africa (2002 data)

Grain	Production ($t \times 10^3$)	Production area ($ha \times 10^3$)	Yield ($t\,ha^{-1}$)	Top three producing countries (descending order)
Cereals				
Cereals (total)	115 757	94 049	1.23	Nigeria, Egypt, South Africa
Barley	3545	3626	0.98	Morocco, Ethiopia, Algeria
Fonio	252	347	0.73	Guinea, Nigeria, Ivory Coast
Maize	42 561	26 936	1.58	South Africa, Egypt, Nigeria
Millet[a]	13 633	20 626	0.66	Nigeria, Niger, Mali
Oats	136	155	0.88	Algeria, Ethiopia, South Africa
Rice (paddy)	17 034	8555	1.99	Egypt, Nigeria, Madagascar
Rye	34	40	0.84	Egypt, Morocco, South Africa
Sorghum	20 309	23 585	0.86	Nigeria, Sudan, Ethiopia
Wheat	16 287	7992	2.04	Egypt, Morocco, South Africa
Pulses (grain legumes)				
Pulses (total)	9208	17 136	0.54	Nigeria, Ethiopia, Uganda
Bambara bean	59	77	0.76	Burkina Faso, Mali[b]
Drybeans (*Phaseolus* beans)	2417	3605	0.67	Uganda, Tanzania, Burundi
Broad bean	1132	835	1.36	Ethiopia, Egypt, Morocco
Chickpea	354	494	0.72	Ethiopia, Morocco, Malawi
Cowpea	3441	8759	0.39	Nigeria, Niger, Burkina Faso
Lentil	90	157	0.57	Morocco, Ethiopia, Egypt
Peas (dry)	293	531	0.55	Ethiopia, Congo (DRC), Burundi
Pigeon pea	206	269	0.77	Malawi, Uganda, Tanzania
Oil-rich legumes				
Peanuts (groundnuts) (in shell)	8486	9975	0.85	Nigeria, Sudan, Senegal
Soybean	989	1090	0.91	Nigeria, South Africa, Uganda
Oilseeds				
Rapeseed	118	44	2.65	Algeria, Ethiopia, Tunisia
Sunflower seed	1042	944	1.10	South Africa, Egypt, Tanzania

[a] Predominantly pearl millet.
[b] Only countries listed.

Africa outside the tropics. The top three producers are Egypt, Morocco, and South Africa. Substantial quantities of wheat are also grown in countries in the tropics, in particular Ethiopia and Kenya, with cultivation being carried out at elevated altitudes to attain cooler conditions.

Africa is the home to a number of millet species. Millets are, by definition, small grained cereals. The FAO data (Table 2) only records the millet species fonio (*Digitaria* sp., also known as acha), with the other millets being lumped together under the general heading "millet." Millet production accounts for more than 20% of the total land area under cereal cultivation in Africa. By far the most important millet is pearl millet (*Pennisetum glaucum*), accounting for ~87% of millet production in Africa, and ~8% of the continent's total cereal production. Pearl millet is uniquely able to produce a crop under very low rainfall conditions, with a minimum water requirement of only 300 mm. The other economically important millets in Africa are, in descending order of production: finger millet (*Eleucine coracana*), teff (tef) (*Eragrostis tef*), and guinea millet (*Brachiaria deflexa*). Finger millet, so-called because the grains are borne on finger-like panicles (Figure 4a), is grown throughout sub-Saharan Africa. It is an especially important grain with regard to rural food security on account of its excellent storability, being slightly subject to insect attack.

As can be seen from Table 2, there is also substantial production of barley in Africa, which is produced for both brewing and as a food. There is also limited production of oats and rye.

Production of other grains is dominated by peanuts (groundnuts) at ~8.5 Mt (Table 2). This is related to the fact that peanuts are used both as a food and a source of cooking oil. Production takes place throughout Africa, with 48 countries recorded as significant producers. However, Nigeria produces by far the largest quantity of peanuts, some 2.7 Mt. Concerning the pulses, quantitatively the most important is cowpea (*Vigna unguiculata*), which is indigenous to Africa, with a production of some 3.4 Mt. The major producing countries are those in

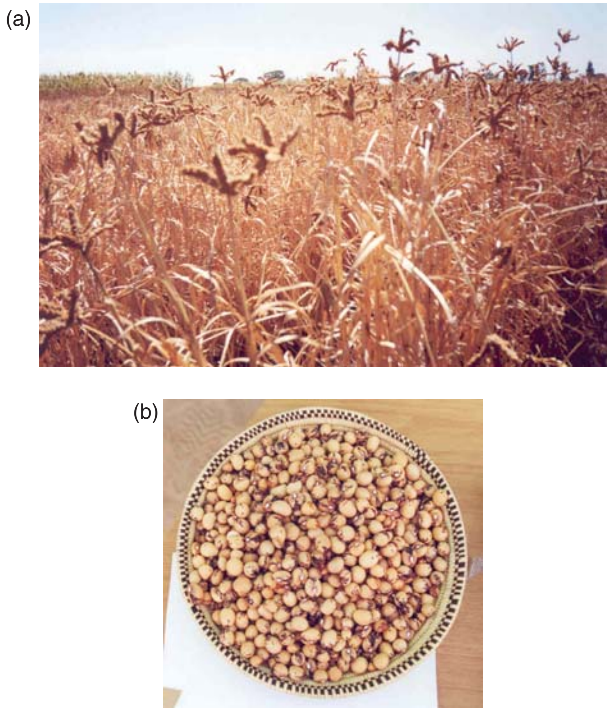

Figure 4 Examples of indigenous African grains important in rural food security: (a) finger millet and (b) bambara bean.

tropical west Africa, in particular Nigeria, although production is widespread throughout Africa. Other quantitatively important pulses are drybeans (*Phaseolus* beans), which originated in South America, and the broad bean, which probably originated in Eurasia. The origin of these beans is reflected by where they are produced. Drybeans are produced very widely across Africa, with significant production taking place in at least 29 countries. However, the major production is in the tropics, with Uganda being the largest producer. In contrast, significant production of broad beans is only in north Africa. The production of other pulses, including chickpea, peas, pigeon pea, and bambara bean, is also of significant importance, especially with regard to rural food security. Of particular interest is the bambara bean (*Vigna subterranea*) (Figure 4b), also known as the African groundnut. The bambara bean, which is indigenous to Africa, can produce a reasonable crop under extreme conditions (drought and poor soil) and is considered by some to be one of the world's most underestimated and underdeveloped crop plants.

Significant quantities of oil-bearing grains, other than peanuts, are also produced in Africa (Table 2). The most important are sunflower and soybean, with a total production of $\sim$2 Mt. There is also some production of rapeseed (canola).

As can been seen from Table 2, agricultural production efficiency in Africa varies very considerably between the grains, with a low of millet at 0.66 t ha^{-1} among the cereals, and an overall low of only 0.39 t ha^{-1} for cowpea and a high of 2.04 t ha^{-1} for wheat among the cereals and an overall high for rapeseed of 2.65 t ha^{-1}. Production efficiency appears to depend, to a considerable extent, on whether the grain is primarily home-processed or industrially processed. In other words, production is driven by the existence and needs of a linked food processing industry. For example, in the case of maize, where in Africa it is mostly milled and made into porridge at home, average yield is only 1.6 t ha^{-1} compared to 8.1 t ha^{-1} in the USA. In contrast, in the case of wheat, which essentially is only milled industrially, the yield in Africa at 2 t ha^{-1} compares reasonably well with the 2.4 t ha^{-1} in the USA.

Consumption

The variety of African grain foods and beverages is huge. There is a vast range of traditional African products, as well as increasingly popular "western" products such as spaghetti, pizza, baked beans, and lager beer.

Traditional African cereal foods include:

- roasted snack foods, e.g., "kollo" – barley (Ethiopia),
- leavened baked wheat flour breads, e.g., "geish baladi" (Egypt),
- leavened steamed wheat flour breads, e.g., "ledombolo" (South Africa),
- flat breads, e.g., "kisra" – sorghum or millet (Sudan),
- pancakes, e.g., "injera" – tef, sorghum, finger millet, wheat or maize, or combinations (Ethiopia),
- dumplings, e.g., "kenkey" – maize (Ghana),
- whole or de-hulled boiled grains, e.g., "supa mtama" – sorghum (Kenya),
- steamed, granulated foods, e.g., "couscous" – wheat, sorghum, or pearl millet (north and west Africa),
- stiff porridges, e.g., "sadza" – maize (Zimbabwe), and "ugali" – maize, sorghum, and millet (east Africa),
- soft porridges and gruels, e.g., "uji" – maize, sorghum, or millet (East Africa),
- porridge cooked with wood ash extract making it alkaline, e.g., to sorghum or millet (Mali),
- porridge, lactic-acid-fermented, making it sour, e.g., "ogi" – maize, sorghum, or millet (Nigeria), and "ting" – sorghum (Botswana and South Africa), and
- porridge flavored with tamarind or lemon juice, making it acidic, e.g., to sorghum (Burkina faso).

Traditional African cereal beverages are both nonalcoholic, e.g., "mageu" (southern Africa) and alcoholic beers, e.g., "pito" (Nigeria) and sorghum beer (central and southern Africa). They are generally opaque and viscous in consistency, due to the presence of semi-suspended starch. Beverages are produced variously from sorghum, maize, pearl millet, and finger millet, either singly or in combination. In the beers, a portion of the cereal is in the form of malt, in order to provide amylase enzymes to hydrolyze the starch into fermentable sugars.

A characteristic of many traditional African cereal foods and beverages is that they have undergone a lactic acid bacterial fermentation during processing. This gives the product a characteristic sharp, sour taste, and helps preserve it against microbial spoilage; examples include the pancake "injera," the dumpling "kenkey," the firm porridge "ting," the thin porridge "ogi," the nonalcoholic beverage "mageu" and sorghum beer.

Legume-based traditional African foods include:

- blanched and roasted whole grain snacks, e.g., "kollo" – chickpea (Ethiopia),
- boiled whole grain snacks, e.g., "nifro" – chickpea, broad bean, or lentil (Ethiopia),
- boiled whole grains foods, e.g., "dikgobe" – cowpea (Botswana), "mayengele" – drybeans (Uganda), and "mtakura" – cowpea, peanuts, or bambara bean (Zimbabwe), all often mixed and served with boiled maize grains,
- steamed pastes, e.g., "moi-moi" – drybeans (Nigeria) and "okpa" – bambara bean (Nigeria),
- deep fried pastes, e.g., "kose" – cowpea or drybeans (Ghana),
- deep fried bean balls, e.g., "akara" – drybeans (Nigeria),
- fermented pastes, e.g., "siljo" – broad bean (Ethiopia),
- boiled grains made into a sauce, e.g., "magila" – cowpea (Uganda),
- germinated and boiled grains made into a sauce, e.g., "azifa" – chickpea, broad bean, or lentil (Ethiopia), and
- dry roasted grain milled into powder, spiced and made into a sauce, e.g., "shiro" – pea, broad bean, or chickpea (Ethiopia).

In most countries in Africa, home processing of grains into foods or the purchase of food produced by vendors "street foods" is the norm. Industrial processing of grains into foods and beverages is in general not as well established or advanced in Africa, as in much of the rest of the world. The exceptions are wheat milling and lager beer brewing, where there are large-scale industrial operations in most countries on the continent. Probably the African countries with the most advanced food processing industries are Egypt, Kenya, Nigeria, South Africa, and Zimbabwe. However, as can be seen even in these countries the scale and sophistication of grain food and beverage processing varies enormously (Figure 5).

Challenges and Opportunities

To prevent increasing poverty and malnutrition, it is essential that the effectiveness of African grain agriculture is improved. Growing dependence on imported grains has a very adverse effect on the fragile economies of many African countries. As an illustration, in 2001 Africa imported some $7.7 billion worth of cereals and cereal products. This was equivalent to nearly $10 per person. This may not seem a lot of money, but it has to be seen in the context that the vast majority of African countries have annual per capita incomes of less than $1000.

The improvement of agriculture in Africa faces a number of severe challenges. These include the acute need to introduce modern agricultural production technologies and chronic environmental problems such as decreasing soil fertility and desertification, resulting from farming more marginal land. There are also socio-political issues. Governmental policies are often not conducive to local agricultural development. Food prices are in some cases kept artificially low, subsidizing the urban consumer, at the cost of the farmer's livelihood. Large-scale farming operations have been, or are threatened with disruption, through inadequate land reforms.

However, probably the greatest challenge is human immunodeficiency virus/acquired immuno deficiency syndrome (HIV/AIDS). For example, at the time of writing (August 2003) the FAO is calling for $43 million to help save and enhance the livelihoods of 6.5 million people in southern Africa affected by the pandemic. The high rates of HIV/AIDS related sickness and death among young adults in southern Africa mean that farming has increasingly to be done by children orphaned by the pandemic and the elderly. Children and the elderly are obviously less capable of hard, physical labor, resulting in declining farming activity.

The application of biotechnology to grain agriculture in Africa has the potential to provide many benefits that could help the continent leapfrog the first Green Revolution. To this end, several African countries have invested very heavily in agricultural biotechnology research and development, and genetically modified organism (GMO) crops are currently (2003) being commercially cultivated in some countries. However, some African countries

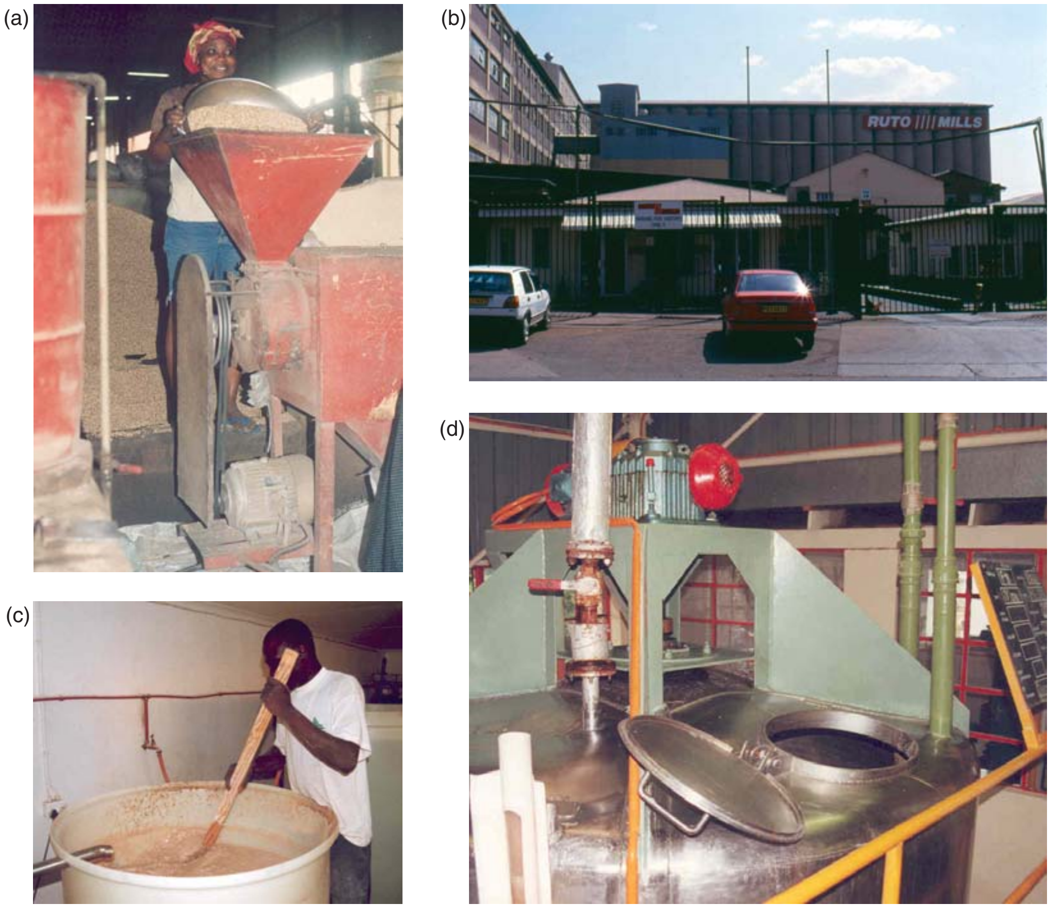

Figure 5 Cereal food and beverage processing in Africa: (a) commercial sorghum milling in Nigeria, (b) industrial maize and wheat mill in South Africa, (c) entrepreneur sorghum beer brewery in South Africa, and (d) industrial sorghum beer brewery in Zimbabwe.

take a different view and refuse to even import GMO grains. Notwithstanding this, GMO plants with "built-in" specific resistant to pests, thereby reducing agricultural input labor requirements and costs; with tolerance to environmental stress enabling crops to be produced on marginal land; and with improved nutritional value, thus combating malnutrition, will be of tremendous value.

Biotechnology will not, however, be a panacea. To improve African agriculture will also require that countries dramatically improve their grain handling systems. Lack of grain storage facilities in many countries causes ruinously low prices for farmers when crops are good and acute shortages for consumers when crops are poor. The almost complete absence of railways and lack of good roads in much of Africa means that the costs of transporting grain from the point of production to where it is processed are very high. This is compounded by high costs of grain assembly, where many small consignments of grain from different small-scale farmers have to be brought to one place to make up a truckload. As a result, locally produced grain is often more expensive than imported grain. There can also be severe problems with quality that render small-scale farmer produced grain unsuitable for industrial processing. For example, consignments of grain may comprise different varieties with differing properties such as grain size, color, and hardness. Worse, the grain may be contaminated with dirt and stones, as a result of threshing on the ground, which damage food processing machinery and contaminate the product.

Rapid urbanization in Africa may be seen as challenge facing agriculture, but it is also presenting an opportunity. The growing urban population is creating a market for quality, value-added, convenience food products. Demand has led to the development of processing industries to produce traditional African foods. The development of the sorghum beer industry in southern Africa is an often-quoted example. More recent examples are the production of instant soy-ogi

in Nigeria and fermented pearl millet flour in Namibia. A perhaps even more exciting development is the manufacture of "western" type products using local grains. Notable examples are the manufacture of malted nonalcoholic beverages in Nigeria, e.g., "Milo" and the brewing of stout and lager beer in Nigeria and also very recently in Uganda, all using locally produced sorghum. In these instances, major multinational companies have been responsible. In doing so, they have created systems for the production of quality grain and more stable markets for the grain, thus helping to develop more efficient and profitable local agriculture.
